Notices
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

The first edition of *Oh's Intensive Care Manual* was published in 1979, when intensive care may not have been in its infancy but it certainly wasn't far beyond. Teik Oh, with tremendous foresight, brought together the fundamental elements of managing the critically ill in a particularly pragmatic manner, which could be considered a guideline for the development of the specialty. Thirty-four years on, the seventh edition reflects both the maturation of that specialty and the phenomenal progress medically, technically, scientifically, ethically and educationally in all areas of management of the critically ill.

As with previous editions, each and every chapter has been updated, and there are many areas where new sections reflect the changing nature of the specialty and the subtle shifts in emphasis in the workplace. These include the growing interest in critical care both before and after the intensive care unit, including the role of palliative care. There is increasing focus on the ethical dilemmas, which cannot be separated from legal considerations that beset critical care in all age groups. Team working is fundamental to delivering intensive care and this is formally addressed, as is education and examination. As bedside ultrasound has been incorporated into clinical examination and many procedures, this is now recognised in addition to the chapter on echocardiography. Extracorporeal membrane oxygenation (ECMO) is increasingly being used for both respiratory and circulatory support, with a unique double chapter dedicated to this area. Almost every chapter has new developments while in some, such as liver failure, there are new sections to address the increasing complexity of the field as it impacts on intensive care. Malignant disease is a common co-morbidity or cause for admission postoperatively so this has been included, as has delirium, which is a common problem.

There has been discussion about the relevance of the paediatric section in this era of specialisation. It is the editors' contention that populations outside of hospital include paediatrics and so a working knowledge of paediatric intensive care should be an integral part of any intensivist's knowledge. With this in mind, this section has been significantly, and in our opinion impressively, updated.

We sincerely hope that this edition will achieve several goals. It will update the previous edition in terms of the changing knowledge base, it will address emerging issues in intensive care, it will be of use to both medical and paramedical staff, but most importantly it will adhere to the pragmatic and clinically useful style so effectively promulgated by Teik Oh when it was originally published 34 years ago. If clinicians can reach for it in the early hours of the morning, easily locate the information they require and feel either guided or reassured, it will have served its purpose. If those passing examinations can say it helped, that would be gilding the lily.

NS

ACKNOWLEDGEMENTS

It is a fitting time to use this opportunity to acknowledge the tremendous achievement of Teik Oh in the creation of this book back in 1979 and for many editions following. It has been a massive asset in the development of the specialty, especially in the early days, and there are hundreds, indeed thousands, of intensivists across much of the world, including both of us, who have been the benefactors of the enthusiasm, energy and sheer work that Teik put into this book. The real beneficiaries have been the countless patients over all those years whose management was enhanced by access to this book either during training or when it has been reached for on the intensive care unit.

Organisation Aspects

This page intentionally left blank

1

Design and organisation of intensive care units

Vineet V Sarode and Felicity H Hawker

The intensive care unit (ICU) is a distinct organisational and geographic entity for clinical activity and care, operating in cooperation with other departments integrated in a hospital. The ICU is used to monitor and support threatened or failing vital functions in critically ill patients, who have illnesses with the potential to endanger life, so that adequate diagnostic measures and medical or surgical therapies can be performed to improve outcome.[1] Hence intensive care patients may be:

1. Patients requiring monitoring and treatment because one or more vital functions are threatened by an acute (or an acute-on-chronic) disease (e.g. sepsis, myocardial infarction, gastrointestinal haemorrhage), or by the sequelae of surgical or other intensive treatment (e.g. percutaneous interventions) with the potential for developing life-threatening conditions
2. Patients already having failure of one or more vital functions such as cardiovascular, respiratory, renal, metabolic, or cerebral function but with a reasonable chance of a meaningful functional recovery. In principle, patients in known end-stages of untreatable terminal diseases are not admitted.

ICUs developed from the postoperative recovery rooms and respiratory units of the mid twentieth century when it became clear that concentrating the sickest patients in one area was beneficial. Intermittent positive-pressure ventilation (IPPV) was pioneered in the treatment of respiratory failure in the 1948–9 poliomyelitis epidemics, and particularly in the 1952 Copenhagen poliomyelitis epidemic when IPPV was delivered using an endotracheal tube and a manual bag, before the development of manual ventilators.

As outlined below, the ICU is a department with dedicated medical, nursing and allied health staff that operates with defined policies and procedures and has its own quality improvement, continuing education and research programmes. Through its care of critically ill patients in the ICU and its outreach activities (see Ch. 2), the intensive care department provides an integrated service to the hospital, without which many programmes (e.g. cardiac surgery, trauma and transplantation) could not function.

CLASSIFICATION AND ROLE DELINEATION OF AN ICU

The delineation of roles of hospitals in a region or area is necessary to rationalise services and optimise resources. Each ICU should similarly have its role in the region defined, and should support the defined duties of its hospital. In general, small hospitals require ICUs that provide basic intensive care services. Critically ill patients who need complex management and sophisticated investigative back-up should be managed in an ICU located in a large tertiary referral hospital. Three levels of adult ICUs are classified as follows by the College of Intensive Care Medicine (Australia and New Zealand).[2] The European Society of Intensive Care Medicine has a similar classification. The American College of Critical Care Medicine also has a similar classification but uses a reversed-numbering system.[3] It should be noted that full-time directors and directors with qualifications in intensive care medicine are less common in the USA,[4] as are the requirements for a dedicated doctor for the ICU around the clock, and referral to the attending ICU specialist for management.[5] Nurse staffing should be in line with accepted standards that are outlined in Chapter 6, Critical Care Nursing.

1. *Level I ICU*: a Level I ICU has a role in small district hospitals. It should be able to provide resuscitation and short-term cardiorespiratory support of critically ill patients. It will have a major role in monitoring and preventing complications in 'at-risk' medical and surgical patients. It must be capable of providing mechanical ventilation and simple invasive cardiovascular monitoring for a period of several hours. A Level I ICU should have an established relationship with a Level II or a Level III unit that should include mutual transfer and back transfer policies and an established joint review process. The medical director should be a certified intensive care specialist.
2. *Level II ICU*: a Level II ICU is located in larger general hospitals. It should be capable of providing a high standard of general intensive care, including multisystem life support, in accordance with the role of its hospital (e.g. regional centre for acute medicine,

general surgery, trauma). It should have a medical officer on site and access to pharmacy, pathology and radiology facilities at all times, but it may not have all forms of complex therapy and investigations (e.g. interventional radiology, cardiac surgical service). The medical director and at least one other specialist should be certified intensive care specialists. Patients admitted must be referred to the attending intensive care specialists for management. Referral and transport policies should be in place with a Level III unit to enable escalation of care.

3. *Level III ICU*: a Level III ICU is located in a major tertiary referral hospital. It should provide all aspects of intensive care management required by its referral role for indefinite periods. These units should have a demonstrated commitment to education and research. Large ICUs should be divided into smaller 'pods' of 8–15 patients for the purpose of clinical management. The unit should be staffed by intensive care specialists with trainees, critical care nurses, allied health professionals and clerical and scientific staff. Complex investigations and imaging and support by specialists of all disciplines required by the referral role of the hospital must be available at all times. All patients admitted to the unit must be referred to the attending intensive care specialist for management.

The classification of types of ICU must not be confused with the description of intensive care beds within a hospital, as with the UK classification of intensive care beds.

TYPE AND SIZE OF AN ICU

An institution may organise its intensive care beds into multiple units under separate management by single-discipline specialists (e.g. medical ICU, surgical ICU, burns ICU). Although this may be functional in some hospitals, the experience in Australia and New Zealand has favoured the development of general multidisciplinary ICUs. Thus, with the exception of dialysis units, coronary care units and neonatal ICUs, critically ill patients are admitted to the hospital's multidisciplinary ICU and are managed by intensive care specialists (or paediatric intensive care specialists in paediatric hospitals).

There are good economic and operational arguments for a multidisciplinary ICU as against separate, single-discipline ICUs. Duplication of equipment and services is avoided. Critically ill patients develop the same pathophysiological processes no matter whether they are classified as medical or surgical and they require the same approaches to support of vital organs.

The ICU may constitute up to 10% of total hospital beds. The number of beds required depends on the role and type of ICU. Multidisciplinary ICUs require more beds than single-specialty ICUs, especially if high-dependency beds are integrated into the unit. ICUs with fewer than four beds are considered not to be cost-effective and are too small to provide adequate clinical experience for skills maintenance for medical and nursing staff. On the other hand, the emerging trend of very large ICUs[6] can create major management problems. There is a suggestion that efficiency deteriorates once the number of critically ill patients per medical team exceeds 12.[7] Consequently as detailed above these unit should be divided into 'pods'. Cohorting of patients in these subunits may be based on specific processes of care or the underlying clinical problem.

HIGH-DEPENDENCY UNIT (HDU)[8–10]

An HDU is a specially staffed and equipped area of a hospital that provides a level of care intermediate between intensive care and the general ward care. Although HDUs may be located in or near specialty wards, increasingly they are located within or immediately adjacent to an ICU complex and are often staffed by the ICU.

The HDU provides invasive monitoring and support for patients with or at risk of developing acute (or acute-on-chronic) single-organ failure, particularly where the predicted risk of clinical deterioration is high or unknown. It may act as a 'step-up' or 'step-down' unit between the level of care delivered on a general ward and that in an ICU. Equipment should be available to manage short-term emergencies (e.g. need for mechanical ventilation). Earlier studies have shown conflicting results about benefits to outcome associated with the introduction of HDUs,[8] whereas a more recent survey where HDU care was based on a 'single-organ failure and support model' has shown that HDUs play a crucial role in management.[10]

DESIGN OF AN ICU

The goal of design is to create a healing environment – a design that produces a measurable improvement in the physical or psychological states of patients, staff and visitors. Optimal ICU design helps to reduce medical errors, improve patient outcomes, reduce length of stay, increase social support for patients and can play a role in reducing costs.[11]

The layout of the ICU should allow rapid access to relevant acute areas including operating theatres and postoperative areas, the emergency department, functional testing departments (e.g. cardiac catheterisation laboratory, endoscopy) and the medical imaging department. Lines of communication must be available around the clock. Safe transport of critically ill patients to and from the ICU should be facilitated by centrally located, keyed, oversized lifts and doors, and corridors should allow easy passage of beds and equipment. There should be a single entry and exit point, attended by the unit receptionist. Through traffic of goods or

people to other hospital areas must never be allowed. An ICU should have areas and rooms for public reception, patient management and support services. The total area of the unit should be 2.5–3 times the area devoted to patient care.

PATIENT CARE ZONE

An ideal patient room should incorporate three zones: a patient zone, a family zone and a caregiver zone.[11] Each patient bed area in an adult ICU requires a minimum floor space of 20 m^2 with single rooms being larger (at least 25 m^2), to accommodate patient, staff and equipment. There should be at least 2.5 m traffic area beyond the bed area. Single rooms should have an optimal clearance of not less than 1.2 m at the head and the foot of the bed, and not less than 1.8 m on each side. The ratio of single-room beds to open-ward beds will depend on the role and type of the ICU. Single rooms are essential for isolation; with the emergence of resistant bacterial strains in ICUs around the world, single rooms are recommended. They have been shown to decrease acquisition of resistant bacteria and antibiotic use.[12] Isolation rooms should be equipped with an anteroom of at least 3 m^2 for hand washing, gowning and storage of isolation material. Some isolation rooms should be negative-pressure ventilated for contagious respiratory infections. A non-splash hand wash basin with elbow- or foot-operated taps and a hand disinfection facility should be available for each bed.

Bedside service outlets should conform to local standards and requirements (including electrical safety and emergency supply, such as to the Australian Standard, Cardiac Protected Status AS3003).

Utilities per bed space as recommended for a Level III ICU are:

- 4 oxygen
- 3 air outlets
- 3 suction inlets
- 16–20 power outlets
- a bedside light
- 4 data outlets.

Adequate and appropriate lighting for clinical observation must be available. Patients should be able to be seen at all the times to allow detection of changes in status. All patient rooms should have access to natural light. Patients exposed to sunlight have been shown to experience less stress, require fewer analgesics and have improved sleep quality and quantity.[13] Lack of natural light or outside view increases the incidence of disorientation in patients and stress levels in staff.[14,15]

Efforts should be made to reduce sound transmission and therefore noise levels (e.g. walls and ceilings should be constructed of materials with high sound-absorbing capability). Suitable and safe air quality should be maintained at all times. Air conditioning and heating should be provided with an emphasis on patient comfort. A clock and a calendar at each bed space are useful for patient orientation. It is widely held that transporting long-stay ICU patients outdoors is good for their morale, and access to an outside area should be considered in the design process.

The medical utility distribution systems configuration (e.g. floor column, wall mounted, or ceiling pendant) depends on individual preference. There should be room to place or attach additional portable monitoring equipment and, as far as possible, equipment should be kept off the floor. Space for charts, syringes, sampling tubes, pillows, suction catheters and patient personal belongings should be available, often in one or more moveable bedside trolleys.

CLINICAL SUPPORT ZONE

Since critical care nursing is primarily at the bedside, staffing of a central nurse station is less important and emphasis should be on ‘decentralised’ stations just inside the room or outside the room – often paired to permit observation of two adjacent rooms. Nevertheless, the central station and other work areas should have adequate space for staff to allow centralised clinical management, staff interaction, mentoring and socialisation. This central station usually houses a central monitor, satellite pharmacy and drug preparation area, satellite storage of sterile and non-sterile items, telephones, computers with internet connections, patient records, reference books and policy and procedure manuals. A dedicated computer for the picture archive and communication system (PACS) or a multi-display X-ray viewer should be located within the patient care area.

UNIT SUPPORT ZONE

Storage areas should take up a total floor space of at least 10 m^2 per bed.[11] They should have separate access remote from the patient area for deliveries, and be no farther than 30 m from the patient area. Frequently used items (e.g. intravenous fluids and giving sets, sheets and dressing trays) should be located closer to patients than infrequently used or non-patient items. There should be an area for storing emergency and transport equipment within the patient area with easy access to all beds.

Two separate spaces for clean (15 m^2) and dirty (25 m^2) utility rooms with separate access are necessary. Facilities for estimating blood gases, glucose, electrolytes, haemoglobin, lactate and sometimes clotting status are usually sufficient for the unit's laboratory. There should be a pneumatic tube or equivalent system to transfer specimens to pathology. Adequate arrangements for offices (receptionist, medical and nursing), doctor-on-call rooms (15 m^2), staff lounge (with food/drinks facilities) (40 m^2 per eight beds), wash rooms and seminar room (40 m^2) should be

available and an interview room should be taken into consideration.

EQUIPMENT

The type and quantity of equipment will vary with the type, size and function of the ICU and must be appropriate to the workload of the unit. There must be a regular programme in place for checking its safety. Protocols and in-service training for medical and nursing staff must be available for the use of all equipment, including steps to be taken in the event of malfunction. There should also be a system in place for regular maintenance and service. The intensive care budget should include provision to replace old or obsolete equipment at appropriate times. A system of stock control should be in place to ensure consumables are always in adequate supply. The ICU director should have a major role in the purchase of new equipment to ensure it is appropriate for the activities of the unit. Level II and III ICUs should have an equipment officer to coordinate these activities.

FAMILY SUPPORT ZONE

For relatives, there should be a separate area of at least 10 m^2 per eight beds (two chairs per bed), and an additional facility with bed and shower as sleep or rest cubicles can be considered. There should be facilities for tea/coffee making and a water dispenser, and toilets should be located close by. Television and/or music should be provided. It is desirable to have separate entrances to the ICU for visitors and health care professionals. One or more separate areas for distressed relatives should be available.

ICU ORGANISATION

STAFFING[1,2,5,6,11,12,15]

The level of staffing depends on the type of hospital, and tertiary hospital ICUs require large teams. Whatever the size of the team, it is crucial that there is clear and proper communication and collaboration among team members and a true multidisciplinary approach. Knaus et al in a classic study[16] first showed the importance of the relationship between the degree of coordination in an ICU and the effectiveness of its care. Other studies have shown relationships between collaboration and teamwork and better outcomes for patients and staff.[17,18] Inadequate communication is the most frequent root cause of sentinel events.[19]

MEDICAL STAFF[20]

An intensive care department should have a medical director who is qualified in intensive care medicine and who coordinates the clinical, administrative and educational activities of the department. The duties of the director should involve patient care, supervision of trainees/other junior doctors, the drafting of diagnostic and therapeutic protocols, responsibility for the quality, safety and appropriateness of care provided and education, training and research. It is recommended that the director be full time in the department.

The director should be supported by a group of other specialists trained in intensive care medicine who provide patient care and contribute to non-clinical activities. In an ICU of Level II or III there must be at least one specialist exclusively rostered to the unit at all times. Specialists should have a significant or full-time commitment to the ICU ahead of clinical commitments elsewhere. There should be sufficient numbers to allow reasonable working hours, protected non-clinical time and leave of all types. Participation in ICU outreach activities (rapid response calls, outpatient review; see Ch. 2) has increased the workload of intensive care specialists as well as junior staff in many hospitals, resulting in the need to increase the size of the medical team.

There should also be at least one junior doctor with an appropriate level of experience rostered exclusively to Level II and III units at all times. Junior medical staff in the ICU may be intensive care trainees, but should ideally also include trainees of other acute disciplines (e.g. anaesthesia, medicine, surgery and emergency medicine). It is imperative that junior doctors are adequately supervised, with specialists being readily available at all times.

Medical work patterns are important for quality of treatment and should be supervised by the director. These patterns include rosters, structure of handover and daily rounds. Appropriate rostering influences satisfaction and avoids burnout syndrome in staff. It reduces tiredness after night shifts or long shifts and consequently improves attention and reduces errors. It also improves the quality of information transfer during handovers and daily rounds.[21]

This physician-staffing model has been used in Australia and New Zealand for many years, but has not been common in the USA. A systematic review[22] has shown that when there has been mandatory intensive care specialist consultation (or closed ICU), compared with no or elective intensive care specialist consultation or open ICU, both ICU and hospital survival were improved and there was a reduced length of stay in ICU and in hospital.

NURSING STAFF

Critical care nursing is covered in Chapter 6. The bedside nurse conducts the majority of patient assessment, evaluation and care in an ICU. When leave of all kinds is factored in, long-term 24-hour cover of a single bed requires a staff complement of six nurses. Nurse shortages have been shown to be associated with increased patient mortality and nurse burnout, and adversely affect outcome and job satisfaction in the ICU.[23,24]

There should be a nurse manager who is appointed with authority and responsibility for the appropriateness of nursing care and who has extensive experience in intensive care nursing as well as managerial experience. In tertiary units the nurse manager should participate in teaching, continuing education and research. Ideally, all nurses working in an ICU should have training and certification in critical care nursing.

ALLIED HEALTH

Access to physiotherapists, dietitians, social workers and other therapists should also be available. A dedicated ward clinical pharmacist is invaluable and participation of a pharmacist on ward rounds has been associated with a reduction in adverse drug events.[25] Respiratory therapists are allied health personnel trained in and responsible for the equipment and clinical aspects of respiratory therapy, a concept well established in North America, but not the UK, continental Europe and Australasia. Technical support staff, either members of the ICU staff or seconded from biomedical departments, is necessary to service, repair and develop equipment.

OTHER STAFF

Provision should be made for adequate secretarial support.[15] Transport and 'lifting' orderly teams will reduce physical stress and possible injuries to nurses and doctors. If no mechanical system is available to transport specimens to the laboratories (e.g. air-pressurised chutes), sufficient and reliable couriers must be provided to do this day and night. The cleaning personnel should be familiar with the ICU environment and infection control protocols. There should also be a point of contact for local interpreters, chaplains, priests or officials of all religions when there is need for their services.

CLINICAL ACTIVITIES

OPERATIONAL POLICIES[2]

Clear-cut administrative policies are vital to the functioning of an ICU. An *open* ICU has unrestricted access to multiple doctors who are allowed to admit and manage their patients. A *closed* ICU has admission, discharge and referral policies under the control of intensive care specialists. Improved cost benefits are likely with a closed ICU and patient outcomes are better, especially if the intensive care specialists have full clinical responsibilities.[22,26] Consequently ICUs should be *closed* under the charge of a medical specialist director. All patients admitted to the ICU are referred to the director and his/her specialist staff for management, although it is important for the ICU team to communicate regularly with the parent unit and to make referrals to other specialty units when appropriate.

There must be clearly defined policies for admission, discharge, management and referral of patients. Lines of responsibilities must be delineated for all staff members and their job descriptions defined. The director must have final overall authority for all staff and their actions, although in other respects each group may be responsible to respective hospital heads (e.g. the Director of Nursing).

Policies for the care of patients should be formulated and standardised. They should be unambiguous, periodically reviewed and familiarised by all staff. Examples include infection control and isolation policies, policies for intra- and inter-facility transport, end-of-life policies (e.g. do not resuscitate (DNR) procedure) and sedation and restraint protocols. A rigorous fire safety and evacuation plan should be in place. It should be noted, however, that when protocols involve complex issues (such as weaning from mechanical ventilation) they might be less efficient than the judgement of experienced clinicians.[27] Clinical management protocols (e.g. for feeding and bowel care) can be laminated and placed in a folder at each bed or loaded on to the intranet.

PATIENT CARE

ICU patient management should be multidisciplinary, with medical, nursing and other staff working together to provide the best care for each patient. The critical care nurse is the primary carer at the bedside and monitors, manages and supports the critically ill patient (see Ch. 6). The medical team consists of one or more registrars, residents or fellows who direct medical care with an intensive care specialist. The patient should be assessed by a formal ward round of the multidisciplinary team twice daily, usually at a time when the junior medical staff members are handing over. The nurse coordinating the floor, pharmacists and dietitians should also take part in daily rounds. Each patient should be assessed clinically (examination, observations and pathology, radiological and other investigation results), the medication chart reviewed, progress determined and a management plan developed for the immediate and longer term. The ward round is also an opportunity to assess compliance with checklists such as Fast Hug (Feeding Analgesia Sedation Thromboembolic prophylaxis Head of bed elevation stress Ulcer prophylaxis Glyceamic control).[28] Clearly, unstable patients will require much more frequent assessment and intervention.

It is crucial that all observations, examination findings, investigations, medical orders, management plans (including treatment limitations) and important communications with other medical teams and patients' families are clearly documented in the appropriate chart or part of the medical record either electronically or in writing.

Wherever possible clinical management should be evidence based and derived through consensus of the members of the ICU team, accepting, however, that evidence-based medicine has limitations when applied to intensive care medicine.[29]

Well-structured collaboration among physicians, nurses and the other professionals is essential for best

possible patient care, which includes presence of inter-professional clinical rounds, standardised and structured processes of handover of inter-disciplinary and inter-professional information and use of clinical information systems.[1]

CARE OF FAMILIES[30]

ICU care includes sensitive handling of relatives. It is important that there are early and repeated discussions with patients' families to reduce family stress and improve consistency in communication. Ideally one senior doctor should be identified as the ICU representative to liaise with a particular family. Discussions should be interactive and honest and an attempt made to predict the likely course, especially with respect to outcome, potential complications and the duration of intensive care management required. The time, date and discussion of each interview should be recorded. Cultural factors should be acknowledged and spiritual support available, especially before, during and after a death. Open visiting hours allow families maximum contact with their loved one and promote an atmosphere of openness and transparency.

OUTREACH

ICU outreach activities are described in Chapter 2.

NON-CLINICAL ACTIVITIES[2]

Non-clinical activities are very important in the ICU, as they enhance the safety, quality and currency of patient care. The College of Intensive Care Medicine recommends that full-time intensive care specialists should have as protected non-clinical time three sessions per fortnight.[20] Nursing and allied health staff should also seek protected time for these activities.

QUALITY IMPROVEMENT[31,32]

It is essential that staff members promote a culture of quality improvement (QI) within the ICU, whatever its size and role. Every ICU should maintain a database that is sufficiently well structured to allow easy extraction of benchmarking, quality control and research data. All ICUs should have demonstrable and documented formal audit and review of its processes and outcomes in a regular multidisciplinary forum. Staff members who collect and process the data should have dedicated QI time.

There are three types of quality indicators:

1. *Structure:* structural indicators assess whether the ICU functions according to its operational guidelines and conforms to the policies of training and specialist bodies (e.g. clinical work load and case mix, staffing establishment and levels of supervision).
2. *Clinical processes*: clinical process indicators assess the way care is delivered. Examples include whether deep-vein thrombosis prophylaxis is given, time to administration of antibiotics and glycaemic control.
3. *Outcomes*: examples of outcome measures include survival rate, quality of life of survivors and patient satisfaction.

The QI process involves *identification* of the indicator to be improved (e.g. high ventilator-associated pneumonia (VAP) rate), *development* of a method to improve it (e.g. checklist such as Fast Hug[28]), *implementation* of the method to improve it (e.g. requirement to tick off the checklist on the morning ward round), and re-evaluation of the indicator (e.g. VAP rate) to ensure the intervention has improved the outcome and finally to *ensure sustainability* (e.g. print checklist on ICU chart).

Activities that assess processes include clinical audit, compliance with protocols, guidelines and checklists and critical incident reporting. Activities that assess outcomes are calculating risk-adjusted mortality using a scoring system such as the Acute Physiology and Chronic Health Evaluation III (APACHE III) and calculation of standardised mortality ratios (see Ch. 3), measurement of rates of adverse events, and surveys.

Risk management is a closely related field. In the ICU, risks can be identified from critical incident reports, morbidity and mortality reviews and complaints from staff, patients or family members. Using similar methodology to the QI process, risks must be identified, assessed and analysed, managed and re-evaluated. A major patient safety incident should result in a root cause analysis.

EDUCATION

All ICUs should have a documented orientation programme for new staff. There should be educational programmes for medical staff and a formal nursing education programme. Educational activities for intensive care trainees include lectures, tutorials, bedside teaching and trial examinations. Clinical reviews and meetings to review journals and new developments should be held regularly. Regular assessments for advanced life support and sometimes other assessments (e.g. medication safety) are often required. Increasingly, simulation centres are used to teach and assess skills and teamwork in crisis scenarios.[33] A number of ICUs are also involved in undergraduate medical teaching. All staff should also participate in continuing education activities outside the hospital (e.g. local, national or international meetings) and specialists should be involved in College CPD.

RESEARCH

Level III ICUs should have an active research programme, preferably with dedicated research staff, but all units should attempt to undertake some research projects whether these are unit-based or contributions to multicentre trials.

THE FUTURE

In the USA critical care medicine is thought to account for 1–2% of the gross domestic product[34] and has

become increasingly used and prominent in the delivery of health care. Although the total number of hospitals, hospital beds and inpatient days has decreased, there has been shown to be a large increase in the number of intensive care beds and bed days.[35] There is every reason to expect that other developed countries will follow this trend. As ICUs become larger and ICU staff numbers become larger still, it is crucial that the basic principles outlined in this chapter are followed and that standards of ICU design, staffing and clinical and non-clinical activities are maintained.

Critical care outreach and rapid response systems

John R Welch and Christian P Subbe

Hospitals around the world are increasingly deploying dedicated outreach, medical emergency or rapid response teams to provide 'critical care without walls'.[1] The objective is to 'ensure equity of care for all critically ill patients irrespective of their location',[2] particularly focusing on those with potential or actual critical illness in general wards.

Outreach and similar services are key components of what are known as rapid response systems. These are based on multidisciplinary 'collaboration and partnership between critical care and other departments to ensure a continuum of care for patients, and [on enhancing] the skills and understanding of all staff in the delivery of critical care'.[3] However, such services are not a replacement for insufficient critical care beds or under-resourced wards.

BACKGROUND

Critical care units contain a small proportion of all hospital beds and have high rates of occupancy. Hospital admission criteria have become more stringent and lengths of stay have decreased in recent years. The result is that many ward patients have serious medical problems but only the most unstable gain admission to a critical care unit. Hence many at-risk patients remain in areas with staff inexperienced in managing critical illness. The problem has been compounded by changes in nursing education that have reduced training time in acute and critical care areas. Key tasks such as measuring physiological signs are often delegated to untrained staff who may not understand the significance of abnormal values; added to this many hospitals use temporary staff less likely to provide the continuity and team working essential for effective care. Medical education is also problematic;[4] training is shorter and more specialised than before, and even senior doctors may be relatively inexperienced.[5]

Comparisons of outcomes of patients admitted to a critical care unit from either the emergency department, operating theatre/recovery area or the wards show that those coming from wards have the highest mortality.[6] Suboptimal treatment is common before transfer to critical care, and is associated with worse outcomes.[7,8] Crucially, differences in mortality have been shown to be due to variations in care rather than differences between the patients themselves and the longer patients are in hospital before admission to critical care, the higher is their mortality.[7,9] Management is often performed by junior teams that fail to appreciate clinical urgency and the importance of senior advice. Inadequate supervision, poor organisation, gaps in communication and continuity of care are also factors.[7,8,10]

Patients who experience lengthy periods of instability before there is an effective medical response are said to have suffered 'failure to rescue'. Such failures are common.[7,8,10–12] In a national review of medical patients subsequently transferred to a critical care unit, many had sustained up to 72 hours of physiological instability.[8] Analysis of 1000 deaths in 10 hospitals concluded that 52 deaths would have had a 50% or greater chance of being prevented; although it is noteworthy that most of these preventable deaths were in elderly, frail patients judged to have had a life expectancy of less than 12 months.[13]

Other groups of patients at risk are those recently discharged from the critical care unit or from the operating theatre after major surgery: about one-quarter of all 'critical care deaths' occur after discharge back to the ward. In particular, patients discharged prematurely suffer increased mortality.[14,15]

OUTREACH, MEDICAL EMERGENCY AND RAPID RESPONSE TEAMS

Medical emergency teams (METs) were introduced in Australia in the 1990s, usually comprising critical care residents and medical registrars. These teams could be directly activated by any member of staff bypassing traditional hospital hierarchies. METs expanded the role of the cardiac arrest team to include the pre-arrest period, generally using call-out criteria based on deranged physiological values or staff concern.[16] In the UK, a review of critical care services in 2000[17] led to increased funding for critical care beds and also the creation of critical care outreach teams, largely staffed by critical care nurses. Similar services have emerged in the USA, driven by the Institute for Healthcare Improvement[18] with more consideration of a whole 'rapid response system' (RRS). This highlights the principle that it is necessary to develop complete, coordinated systems to avoid failures to rescue reliably and consistently.

The RRS can be divided into:

- an afferent component designed to ensure timely escalation of the deteriorating patient, usually using agreed physiological values as a trigger
- an efferent component comprising an individual or team of clinicians who can promptly respond to deterioration
- governance and administrative structures to oversee and organise the service and its ways of working
- mechanisms to improve hospital processes.[19]

Another approach is to think of the RRS as being built on development of a 'chain of prevention' made up of education, monitoring, recognition, call and response.[20]

There are now many models and terms used.[19,21] METs are usually physician led. Critical care outreach (CCO) and rapid response teams (RRTs) are typically nurse led, but may also include physiotherapists and other allied health professionals as well as doctors. Most teams respond to defined physiological triggers, although some also work proactively with known at-risk patients such as those discharged from the critical care unit.

The aim is to prevent unnecessary critical care admissions, to ensure timely transfer to the critical care unit when needed, to facilitate safe return to the ward, to share critical care skills,[17] and to improve care throughout the hospital. There may also be a role in support for patients and their families after hospital discharge (**Box 2.1**).

Box 2.1 Functions of critical care outreach

- Identification of at-risk patients
- Support for ward staff caring for at-risk patients and those recovering from critical illness
- Referral pathways for obtaining timely, effective critical care treatments
- Immediate availability of expert critical care and resuscitation skills when required
- Facilitation of timely transfer to a critical care facility when needed
- Education for ward staff in recognition of fundamental signs of deterioration, and in understanding how to obtain appropriate help promptly
- Outpatient support to patients and their families following discharge from hospital
- Development of systems of coordinated, collaborative, continuous care of critically ill and recovering patients across the hospital and also in the community
- Audit and improvement of basic standards of acute and critical care – and of the outreach team itself – to minimise risk and optimise treatment of the critically ill throughout the hospital

Together, these elements comprise a system to deliver safe, quality care with proactive management of risk and timely treatment of critical illness.

RECOGNISING CRITICAL ILLNESS

Patients with potential or actual critical illness can be identified by review of the history, by examination and by investigations. Higher risks are associated with extremes of age, with significant co-morbidities or with serious presenting conditions.

The timeliness of response depends largely on the quality of monitoring. Patients at risk of deterioration require either very frequent or continuous monitoring to optimise the effect of a rapid response intervention. A conference on the afferent limb of the RRS found that: '(1) vital sign aberrations predict risk, (2) monitoring patients more effectively may improve outcome, although some risk is random, (3) the workload implications of monitoring on the clinical workforce have not been explored, but … should be investigated, (4) the characteristics of an ideal monitoring system are identifiable, and it is possible to categorize monitoring modalities. It may also be possible to describe monitoring levels, and a system'.[22] Currently, measuring and recording of vital signs on general wards are often inadequate.[8,10]

For early recognition of deterioration to be effective:

- the physiological values, laboratory results or other data used for patient monitoring should enable timely identification of deterioration
- there must be enough time to identify at-risk patients and then obtain expert assistance before irreversible deterioration has occurred.

ABNORMAL PHYSIOLOGY AND ADVERSE OUTCOME

There is a known association between abnormal physiology and adverse outcomes,[23,24] and critical care severity scoring systems such as APACHE II[25] are based upon this relationship. Patients who suffer cardiopulmonary arrest or who die in hospital generally have abnormal physiological values recorded in the preceding period, as do patients requiring transfer to the critical care unit.[8,10–12,23,24]

The finding that abnormal physiology precedes adverse events has led to key signs being incorporated into various early warning scoring (EWS) systems. These systems use different combinations of parameters including respiratory rate, oxygen saturation, heart rate, blood pressure, temperature and level of consciousness as well as other indicators such as urine output and pain.[26] The patient's measured vital signs are compared with a set of reference values, with measurements above or below designated points used as triggers for escalation. Formats vary but generally use similar approaches, awarding points for varying degrees of derangement of different functions. Improvement or further deterioration can then be tracked by

changes in EWS recorded over time, so that an EWS used in this way can be described as a 'track and trigger system'. Track and trigger systems are broadly categorised as single or multiple parameter systems, aggregate weighted scoring systems or combinations[2] (Box 2.2).

Many different systems with variable trigger thresholds have been developed.[27–29] This variance has led to calls for standardised systems to improve training and reliability of response, with the UK National Early Warning Score (NEWS) published in 2012[30] (Table 2.1) and now adopted in Wales, Ireland and England. It is based on the analysis of a large database of patients' vital signs recorded in different acute hospitals.[31]

A different approach has been taken by Australian METs, where the calling-out criteria are usually based upon single, markedly deranged physiological values, although ward staff concern is also a trigger[32] (Box 2.3).

As well as EWS systems based simply on acute physiology, there are also published methods using other data to risk stratify patients at hospital admission. These systems aim to differentiate patients who need to stay in hospital for further monitoring or treatment and those who need only minimal monitoring or may even be discharged home. Systems based on laboratory parameters alone,[33] laboratory parameters in conjunction with vital sign observations,[34] or indicators of acute physiology, chronic illness and functional status[35] have all been validated against hospital mortality.

Another possible method of activating the RRS is for patients themselves – or their relatives – to call. This method was first used in paediatric settings but may also be useful for adults.[36]

Box 2.2 Classification of track and trigger warning systems[2]

Single-parameter systems
- Tracking: periodic observation of selected basic signs
- Trigger: one or more extreme observational values

Multiple parameter systems
- Tracking: periodic observation of selected basic vital signs
- Trigger: two or more extreme observational values

Aggregate weighted scoring systems
- Tracking: periodic observation of selected basic vital signs and the assignment of weighted scores to physiological values with calculation of a total score
- Trigger: achieving a previously agreed trigger threshold with the total score
- Combination systems
- Elements of single- or multiple-parameter systems in combination with aggregate weighted scoring

MEASURING OUTCOME

The use of critical care outreach and other RRSs is based on the premise that early detection and treatment of critical illness should improve patient outcomes. The quality of these services may be evaluated against such outcomes but also other indicators including process measures (e.g. numbers of trained staff, completeness of bedside observations, timeliness of escalation and speed of response). The time from patient trigger to transfer to a critical care unit – or initiation of critical care treatments on the ward – may be a useful indicator too (i.e. the 'Score-to-Door time'[37]).

Table 2.2 shows one system that can be used to evaluate outcomes of RRS interventions 24 hours after the initial event, with outcomes classified as being either positive or negative. The proportion of positive interventions provides a measure of the quality of the service.

Box 2.3 Medical emergency team calling-out criteria as used in the 23-site MERIT study[32]

Airway	Threatened
Breathing	Respiratory rate <5 or >36 per min Respiratory arrest
Circulation	Systolic blood pressure <90 mmHg (11.97 kPa) Pulse rate <40 or >140 per min
Neurology	Sudden fall in level of consciousness (fall in GCS of >2 points) Repeated or extended seizures
Other	Any patient you are seriously worried about

Table 2.1 National early warning score (NEWS)[31]

PHYSIOLOGICAL PARAMETERS	3	2	1	0	1	2	3
Respiration rate	≤8		9–11	12–20		21–24	≥25
Oxygen saturations	≤91	92–93	94–95	≥96			
Any supplemental oxygen?		Yes		No			
Temperature	≤35.0		35.1–36.0	36.1–38.0	38.1–39.0	≥39.1	
Systolic BP	≤90	91–100	101–110	111–219			≥220
Heart rate	≤40		41–50	51–90	91–110	111–130	≥131
Level of consciousness (AVPU (Alert, Voice, Pain, Unresponsive) scale)				A	V	P	U

Table 2.2 Matrix of possible outcomes of RRS intervention: the '**M**ulti-disciplinary **A**udit **E**va**L**uating **O**utcomes of **R**apid response' (MAELOR) tool

OUTCOMES	POSITIVE	NEGATIVE
Transfer to critical care unit, high-dependency area or operating theatre	1. Timely transfer, e.g. <4 hours after the first trigger	2. Delayed transfer, e.g. >4 hours after the first trigger
Alive on ward	3. No longer triggering	4. Still triggering
Deceased	5. On terminal care pathway/with DNAR order	6. Following cardiopulmonary arrest
Others	7. Alive with documented treatment limitations and DNAR order in place 8. a. Trigger from new pathology unrelated to previous call-out b. Chronic condition leading to continuous trigger (e.g. tachypnoea in advanced pulmonary fibrosis) c. Discharged from hospital	9. Outcome not known/lost to follow-up

Data from Morris A, Owen HM, Jones K, et al. Objective patient-related outcomes of rapid-response systems – a pilot study to demonstrate feasibility in two hospitals. Crit Care Resusc. 2013;15(1):33–9.

RRSs have highlighted shortcomings in the care of ward patients, and contributed to a significant change in attitude to at-risk patients. They have been instrumental in improving ward monitoring, and in disseminating critical care skills. There are anecdotal reports of benefit to individuals,[38] and published evidence that these services improve recognition of at-risk patients, reduce length of stay, cardiac arrest rates, unplanned admissions to critical care, and morbidity and mortality.[39–43] However, some reports do not show significant effects. There are in fact few good quality studies, with just two randomised controlled trials published to date.[32,43]

Positive studies include a UK randomised trial of phased introduction of a 24-hour outreach service to 16 wards in a general acute hospital.[43,44] The outreach team routinely followed up patients discharged from critical care to wards and also saw referrals generated by ward staff concern or use of an EWS system. There was a statistically significant reduction in mortality in wards where the service was operational. In contrast, a large prospective randomised trial of METs in Australia found no improvements in cardiac arrests, unplanned admissions to critical care or unexpected deaths in comparison to the control hospitals in the primary analysis.[32] A secondary analysis was able to show improved outcomes in most hospitals in both the intervention and control groups, with dramatic improvements in those with the weakest baseline performance.[45] This study revealed many shortcomings in identification and care of critically ill patients, with one possible conclusion being that it is essential to take a whole systems approach to early recognition of deterioration and achievement of an effective response.

Several studies have shown an inverse relation between the number of calls to the MET and the rates of cardiac arrest.[46] The explanation for this is not completely clear. It may be that reductions in cardiac arrests are linked to increased proportions of patients surviving to discharge, but it is as likely that decreased cardiac arrest calls are a reflection of better patient assessment and more timely implementation of Do-Not-Attempt-Resuscitation orders and involvement of palliative care specialists in patients with terminal illness. This is not a negative: delivery of good palliative care might be one of the positive outcomes supported by a RRS.[47]

There has been less investigation of the follow-up of patients discharged from critical care units, although this group is known to remain at significant risk. A matched-cohort analysis of 5924 patients found follow-up by an outreach team reduced length of stay and mortality when compared with historical controls and matched patients from hospitals with no outreach.[48]

SETTING UP AN OUTREACH SERVICE

Patients with potential or actual critical care illness are found in every area of the hospital, so systems to identify and treat those patients need to be planned at an organisational level. Involvement of managerial and clinical staff is essential, especially from the wards. It is particularly important that there is agreement and clarity about how the outreach team or equivalent interacts with the parent/primary medical team.

KEY STEPS IN PLANNING AN RRS

- Appoint senior clinical and managerial leads to develop the service.
- Institute organisational needs analysis, audit and evaluation, asking:
  - which patients are at risk of critical illness and where are they located?

- where do cardiopulmonary arrests and unexpected deaths occur?
- what is the source of unplanned admissions to the critical care unit?
- what is the pattern of adverse events where harm can be attributed to the process of care?
- what are the other relevant clinical governance/risk management issues (e.g. complaints), or morbidity and mortality data?

- A point prevalence study can give a snapshot view of the location of patients with physiological derangement.
- Review of unplanned admissions to the critical care unit can identify systems failings including quality of patient management and appropriateness and timeliness of escalation. Key practices can be assessed against specific, measurable standards.
- Such analyses should also highlight staff education and training needs.

Other factors to consider include:

- the patient case-mix
- existing skills of ward staff
- proposed hours of service
- size of hospital – and likely demand
- existing services such as pain teams, nutrition teams, tracheostomy specialist practitioners respiratory specialists, renal specialists, night teams, etc.
- training facilities
- outreach service location and equipment needs including information technology
- funding.

Various bodies in the UK, Australia and USA have published useful guides to setting up and developing a RRS; all are available online.[2,3,49,50]

THE OUTREACH TEAM

The composition and skills of the team should be designed to meet the specific needs identified by individual organisations. At a minimum, the team should be capable of assessment, diagnosis, initiation of resuscitation, and rapid triage of the critically ill patient to a higher level of care with authority to so act. Such clinical competencies as airway management techniques, venepuncture and cannulation are essential, and so are skills in education and training, research and audit. A multiprofessional team is required for this range of skills to be available, and to enable communication with other staff across the hospital. The UK Department of Health has detailed the competencies required for care of at-risk and deteriorating patients, specifying what should be expected of junior, middle-grade and senior staff.[51]

A pragmatic, staged implementation could include:

1. Establishing an education programme in care of the critically ill for ward staff so that they can recognise signs of deterioration and understand the necessity and means of obtaining timely help. Staff should update their skills annually.
2. Introducing a physiological track and trigger warning system and defined referral/response protocols.
3. Developing clinical bedside support – incrementally if necessary – increasing the number of clinical areas covered by the team, and the hours of work. This might include follow-up of patients discharged from critical care and responding to patients identified through the track and trigger system or other means.[2]

It is essential that robust data are collected and used for audit and evaluation – and for feedback to ward managers and clinical staff. Successes should be highlighted and areas for improvement identified. Data may include:

- numbers of referrals and patient follow-ups
- date and time of each episode
- patient details (e.g. age, sex, date of hospital admission, location, emergency/elective admission, medical/surgical, resuscitation status)
- trigger event (e.g. early warning score, cardiac arrest call)
- significant problems identified
- interventions performed
- patient outcomes.

THE FUTURE: TECHNOLOGY TO MITIGATE HUMAN FACTORS

In an increasingly safety conscious society, ‘failure to rescue’ becomes less and less acceptable. It is clear that many of the errors that lead to ‘failure to rescue’ are caused by human factors and flaws in the design of hospital systems.[52–54] This was shown by the MERIT study finding that of patients needing escalation to the critical care unit – with signs that should have been referred to the MET – only 30% were actually referred.[32] Hierarchical thinking, inflexible mental modelling, highly variable performance and uncoordinated, inefficient hospital organisation are all factors.[52–54] Even relatively simple matters such as the documentation for vital sign recording have a role: research from Australia has shown that attention to the layout of charts is likely to promote more reliable detection of deterioration.[55]

Automation has the potential to improve reliability of some key processes. Technological aids that automate calculation of early warning scores and communication of abnormal trigger scores are available. These systems are able to perform calculations of EWS with fewer errors and have been shown to improve outcomes.[56] The development of increasingly sophisticated expert systems will enable analysis of patterns of abnormal vital signs that can produce specific alerts as well as prompts and advice about individual patients, with due consideration of their particular pathophysiology.

CONCLUSION

There is no doubt that there are significant numbers of patients on hospital wards with potential or actual critical illness whose care should and could be improved. The RRS represents one method of addressing these issues. In the future, it may turn out to be that the most useful contribution of RRSs is the highlighting of defects in current ways of working, and the application of what has been learned from RRS initiatives to the whole hospital.

Key features include:

- Deteriorating patients can be identified by careful monitoring of physiological signs.
- Timely escalation of appropriate patients to critical care should improve outcomes.
- Effective response to acute deterioration depends on complex human interactions that are prone to error.
- Rapid response systems standardise the response to at-risk and deteriorating patients, and improve process and clinical outcomes for critically ill patients presenting outside the critical care unit.
- Successful systems are based upon multiprofessional working, and effective communication education, data collection/audit, learning from errors, and planned improvement of whole systems of care.

Severity of illness and likely outcome from critical illness

Mark Palazzo

It is intuitive that severity of illness might be related to eventual outcome. It is also not unreasonable to assume that outcome might also be related to whether a condition is reversible or to the presence of co-morbidities that might modify resilience. However, although acuity may be related to outcome, the speed of delivery of care, its organisation and avoidance of iatrogenicity can also be expected to play their part. Many patients also acquire conditions and complications that they were not admitted with whilst in the intensive care unit (ICU).

In many conditions there has been a long history of attempting to relate acuity to outcome. For example, the New York Heart Association first classified patients with cardiac disease based on clinical severity and prognosis in 1928 and this has subsequently been updated seven times, the last in 1994. Similarly the Glasgow Coma Scale described the changes in coma following head injury and its association with prognosis.[1–3] The Ranson score related outcome to severity of acute pancreatitis,[4] while the Pugh modification of Child–Turcotte classification for patients undergoing porto-systemic shunt surgery is widely used for classification of end-stage liver disease.[5] More recently the Euroscore has been used to calculate likely mortality following cardiac surgery.[6]

The earliest attempt to quantify severity of illness in a heterogeneous critically ill population was by Cullen, who devised a score in which therapeutic intervention was used as a surrogate for illness.[7] This was followed in 1981 with the introduction of the Acute Physiology, Age and Chronic Health Evaluation (APACHE) scoring system and shortly after by the Simplified Acute Physiology Score (SAPS) and Mortality Prediction Model (MPM).[8–10] These scores have since been updated for international use while others have been introduced and calibrated to meet a specific population – such as the ICNARC model for the UK.[11]

The advantages of quantifying critical illness with scores and relating this to outcome include:

- a common language for discussion of severity of illness
- a method by which critical care practice and processes can be compared both within and between units
- provision of risk-adjusted mortality predictions facilitating acuity comparisons for clinical trials
- indication of likely post-ICU morbidity and survival.

Limitations of quantifying critical illness with scores are:

- they cannot provide individual patient prognosis
- they cannot be meaningfully used for treatment decisions.

Although mortality prediction is the focus of scoring systems, the numerically greater burden of critical illness is continuing physical and social disablement; indeed the survivors of critical care have a higher mortality than the normal population. There is an inherent temptation to use scoring systems to indicate an individual patient's prognosis, but this would be statistically incorrect. The scores were derived from very large cohorts of heterogeneous patients and the prognostic output is a mortality probability estimate for a similar cohort not an individual.

Less controversial has been the common use of scoring systems to demonstrate there is balance in the acuity of patients admitted into the arms of a clinical trial, but even there the use of the score rather than the calculated risk of death can be misleading in heterogeneous patient groups.[12] Despite the known controversy in using individual patient scores for predicting outcome, studies have used APACHE II scores as a guide to enrolment for treatment.[13]

It is of interest that, although the critical care community widely accepts acuity scores to demonstrate balance between groups in clinical trials, it is less enthusiastic to accept the same systems as comparators for between unit and between country performances, citing calibration and case mix as confounders.[14] That is unless, of course, the same said individuals' unit performances compare favourably!

Poor calibration (model under or over estimates mortality rate for the cohort under study) can be due to numerous reasons. The patient population may be from a different health system to the one where the model was developed, or there may be a systematic error in documenting the raw data, or the case-mix is very different to the original model, or indeed the model fails

to include an important prognostic variable that is present in the cohort. For example, it has become clearer that prognosis is as much affected by local organisation, patient pathways, patient's pre-admission condition or their location prior to admission as it is by acute physiological disturbances.[15,16]

Scoring systems would be better calibrated if the models were used only on patient populations similar to those from which the models were constructed, but this would limit their international usefulness. An alternative approach would be to develop the model from a wider international cohort, but then such a model could calibrate poorly when used in an individual country. SAPS III (developed internationally) provided a solution to this with customised formulae so that the risk-adjusted expected mortality could be related to geographical location.[16]

Inevitably, as medical services progress and new treatments become available, risk-adjusted mortality predictions become outdated and trend towards overestimated expected mortality.[17,18] Consequently the designers of the scoring systems have reviewed their models every few years. **Table 3.1** outlines some of the upgraded systems.

FACTORS INDICATING SEVERITY OF ILLNESS AND RISKS THAT MIGHT CONTRIBUTE TO OUTCOME

- Acute physiological disturbance
- Primary pathological process causing physiological disturbance
- Age, co-morbid states and 'physiological reserve'
- Location prior to admission and emergency status
- Unit organisation and processes.

ACUTE PHYSIOLOGICAL DISTURBANCE

It is a reasonable assumption that the degree of physiological disturbance may bear some relationship to severity of illness. This is based on the observation that an untreated pathological insult is followed by increasing compensatory activity in order to retain vital organ function. Most compensatory mechanisms are mediated through neuroendocrine responses directed to maintaining tissue oxygenation ensuring mitochondrial and ultimately organ function. Compensatory signs such as hyperventilation, tachycardia and oliguria associated with cerebral dysfunction are hallmarks of early, untreated critical illness and if decompensation ensues hypotension, metabolic acidosis and stupor develop. Regardless of the insult, organs have limited ways in which they manifest dysfunction and decompensation. Quantifying these common responses is a logical starting point for the basis of a generic scoring system. It is notable that some scoring systems such as SAPS are based solely on the acute physiological disturbance with little or no reference to the driving pathology.

However, acute physiological measurements present some challenges if they are to be translated to scores. The relationship between acute response and insult is non-linear; furthermore anatomical organ damage may not be reflected by measured function until quite extensive. For example, the liver and kidney manifest biochemical abnormality only when a significant proportion of organ mass is malfunctioning. Equally we

Table 3.1 Revision dates for the most common internationally recognised risk-adjusted models for mortality prediction

SEVERITY OF ILLNESS MODEL	YEAR	TIMING OF SCORE	COHORT SIZE	ICU UNITS	WORLD REGIONS OF ICUS PARTICIPATING IN DEVELOPMENT OF MODEL
SAPS	1984	1st 24 h	679	8	France
SAPS II	1993	1st 24 h	13,152	137	Europe/USA
SAPS III	2005	Admission	16,784	303	Europe, Australia, South and Central America
MPM I	1987	Admission	1997	1	USA
MPM II_0	1993	Admission	19,124	137	USA/Europe
MPM_0III	2007	Admission	124,855	135	USA/Canada Brazil
APACHE I	1981	1st 24 h	805	2	USA
APACHE II	1985	1st 24 h	5815	13	USA
APACHE III	1991	1st 24 h	17,440	40	USA
APACHE IV	2006	1st 24 h	110,558	104	USA
ICNARC	2007	1st 24 h	216,626	163	UK
ICNARC revised coefficients for APACHE II and ICNARC	2011 model	1st 24 h			UK

have a poor understanding of the equivalency of malfunction between organs (e.g. what degree of acidosis is equivalent to a given tachycardia or hypotension).

A further consideration for severity of illness estimation is its timing. Ideally a true estimate of physiological disturbance would be in an untreated state. Logistically this may be quite difficult, and indeed most scores arbitrarily took the first 24 hours after admission to intensive care as the period to estimate severity of illness. However, logic would dictate that estimates would be more appropriate in the hours prior to admission when fluid resuscitation, early antibiotic treatment, ventilation or inotropes have not had time to modify the acute response or extent of decompensation. Such support for the seriously ill can diminish the difference between such patients and, for example, elective surgical admissions who have for convenience been kept ventilated until reaching the ICU. The risk of underestimating physiological disturbance has been mitigated either by taking account of the organ support on admission or by including estimates of physiological disturbance before support has been commenced. For example, SAPS III makes an adjustment for patients on inotropes, whereas MPM II allows measurements for the hour on either side of admission.[15,16,19]

PRIMARY PATHOLOGICAL PROCESS

It would be expected that, for a given degree of acute physiological disturbance, the most serious primary pathologies are likely to have the worst predicted outcomes. For example, for a given degree of acute respiratory disturbance at admission a patient with community-acquired pneumonia is likely to have a better outcome than an immunosuppressed patient with an unknown opportunist pneumonia. Furthermore, the potential reversibility of a primary pathological process with specific therapies also greatly influences outcome. For example, patients with diabetic ketoacidosis can be extremely unwell, but specific therapy with insulin and volume therapy can rapidly reverse the physiological disturbance. Conversely failure to identify organisms or sources of sepsis delays specific therapy and adversely affects outcome.

Both APACHE and the most recent SAPS systems include diagnostic categories with the acute physiological data to estimate risk of hospital death.

AGE, CO-MORBID STATES AND PHYSIOLOGICAL RESERVE

Increasing age is normally associated with diminishing capacity to respond to an insult and decompensation occurs earlier. However, this capacity is only broadly predictable. 'Biological' age is a vague term used to imply physiological reserve below that expected for a patient's chronological age. Biological age greater than chronological age is commonly perceived in heavy smokers or abusers of alcohol. These patients may or may not have diminished organ function, but are generally expected to more readily reach a decompensated state. Physiological reserve is a term that hints at the likely ability to cope with an insult and its physiological demands, it is often inferred from age and co-morbidity. Conditions such as diabetes and chronic pulmonary disease are generally considered to have some bearing on physiological reserve, but not always as much as might be expected. On the other hand, co-morbid states such as immunosuppression, cirrhosis and haematological malignancies do result in significant diminution of resistance to infection. These co-morbidities are commonly included in critical illness severity scoring systems, unlike diabetes.

LOCATION PRIOR TO ADMISSION AND EMERGENCY STATUS

The location of a patient prior to admission to ICU is a factor recognised by the more recent scoring systems as having an influence on outcome.[11,15] This might in part be because location influences the lead time to definitive treatment, or is a health care environment where the likelihood of carrying resistant organisms is higher.

The emergency status of a patient has equally been recognised by all scoring systems to influence outcome. Acute medical and emergency surgery admissions are associated with poorer outcomes than those following elective surgery.

UNIT ORGANISATION AND PROCESSES

Soon after the introduction of APACHE II it was recognised that units with effective nursing and medical leadership, good communications and dedicated intensive care specialists had better outcomes than those without such characteristics.[20–25] Additionally, factors such as genetic variables, socioeconomic status, access to investigations and normal medical care are likely to have a quantifiable but as yet indeterminate bearing on the widest aspects of outcome.

RISK-ADJUSTED EXPECTED OUTCOME

Prior to the advent of scoring systems, expected outcome from critical illness was not calculated and it was difficult to have confidence that control groups in clinical trials were representative or internationally relevant. The common outcome measures are ICU, 28-day and hospital mortalities. Scoring systems provide calculations which can demonstrate that active and control groups have similar risks of death and, importantly, that the control group had observed outcomes similar to those expected. Similarly risk-adjusted expected outcome is a standard tool for monitoring the performance of an ICU and offers some indication of comparative performance particularly when patient case-mix is similar.

However, whereas hospital death and risk of death is a clear-cut outcome measure, morbidity in the guise of serious psychological or physical functional impairment is far more common.[26–29] Indeed there is a case that risk-adjusted outcome should be extended to consider time to return to normal function or work as well as survival at 1 year.[30,31] Longer-term outcome is confounded by premorbid chronic health status.

PRINCIPLES OF SCORING SYSTEM DESIGN

CHOICE OF INDEPENDENT PHYSIOLOGICAL VARIABLES AND THEIR TIMING

The designers of the APACHE and SAPS systems originally chose physiological variables that they felt would represent measures of acute illness. The variables chosen by experts were weighted equally on a linear scale with the highest value given to the worst physiological deviation from normal.[9,32] In these early models diagnostic details, premorbid conditions, age and emergency status were also included to create a score that was then used in an equation to provide risk of death. Later upgrades to these systems, SAPS, APACHE and MPM, used logistic regression analysis to determine which variables should be included to explain the observed hospital mortality.[33] Variables were no longer given equal importance nor their weightings linearly related to the physiological disturbance. Furthermore this statistical approach to developing a scoring system confirmed that factors suspected of influencing outcome such as location prior to admission, cardiopulmonary resuscitation (CPR) or dependence on inotropes prior to admission indeed had discriminatory power and were included in the logistic regression equation from which risk of death could be calculated.[11,16]

DEVELOPING A SCORING METHODOLOGY AND ITS VALIDATION

All the commonly used acuity scoring systems have been based on large databases derived from several ICUs (see Table 3.1). Typically more than 50% of the database is used to provide a cohort of patients to act as a developmental group. A number of independent categorical or continuous variables that could feasibly influence outcome are collected. These variables are used in a logistic regression equation to achieve the best fit to explain the dichotomous dependent variables survival or hospital death. The starting point is to include all variables that by univariate analysis are moderately related to outcome, perhaps at the $p<0.15$ level. The logistic equation is then modified through multiple iterations during which variables are either removed or combined in order to improve the fit to explaining outcome. Each variable is weighted with a coefficient to provide the best fit that distinguishes survival from non-survival. The best fit is assessed by the Hosmer–Lemeshow test for goodness of fit.[34] The model is initially tested on the developmental cohort. This is done by exploring the model's ability to discriminate between survivors and non-survivors by plotting positive predictions of death against false-positive predictions in a receiver operator curve (see below). The area under the curve (AUC) sometimes referred to as the c-statistic (or concordance index), is a value that varies from 0.5 (discriminating power not better than chance) to 1.0 (perfect discriminating power). Clearly when tested on the developmental cohort the discriminatory power would be expected to be high. This is done through statistical techniques such as 'jack-knifing' or 'boot-strapping' that take numerous small samples of the developmental cohort to demonstrate stability of the chosen variables. The next step is to test the model against a new set of patients, the validation dataset (the other 50% of patients from the database who were not in the developmental set). The aim of validation is to demonstrate that the model can be used to predict likely hospital outcome, which is again measured with the concordance index.

Once a satisfactory equation has been developed it can be used to calculate the overall probability of death for a group of patients.

A perfect model should ideally be able to predict which patients will survive and which will die (discrimination) and correctly predict the overall observed mortality (calibration). Discriminating power is assessed by construction of a receiver operator curve (ROC).

ROC CONSTRUCTION

The area under a ROC is constructed by using the logistic regression model to indicate the number of patients predicted to die and comparing this with the observed numbers who died. This is undertaken at different thresholds of predictions of death. So, for example, if the threshold is set at 50% the assumption is that any patient at or above that calculated risk counts as a prediction to die. This in turn is compared with what actually happened. Clearly many patients predicted to die do die, but a not-insignificant number predicted to die at the 50% threshold will survive. One can determine just how unreliable that threshold is as a predictor by determining the true-positive predictions (sensitivity) – that is, the observed deaths among those who were predicted to die – and compare these with the false-positive predictions – that is, the survivors among all those predicted to die. This exercise can be repeated using different thresholds such as 60, 70, 80, 90% where again it is assumed that those with calculated risks at the threshold value or above would all be predicted to die. At each threshold point the sensitivity and false-positive rates are calculated. The false-positive predictions of death can be reduced only if the model also has high specificity, in other words it correctly predicts

survivors. It is therefore common for the false-positive rate to be expressed as 1 – specificity or 100 – specificity if expressed as percentages. The ROC convention is to plot sensitivity on the *y*-axis against 1 – specificity on the *x*-axis, with each *x* and *y* value representing sensitivity and false-positive rates at each threshold point (**Fig. 3.1**).

A perfect model would be 100% sensitive and 100% specific and would therefore follow the *y*-axis with a sensitivity value of 1 and a false-positive value of 0.

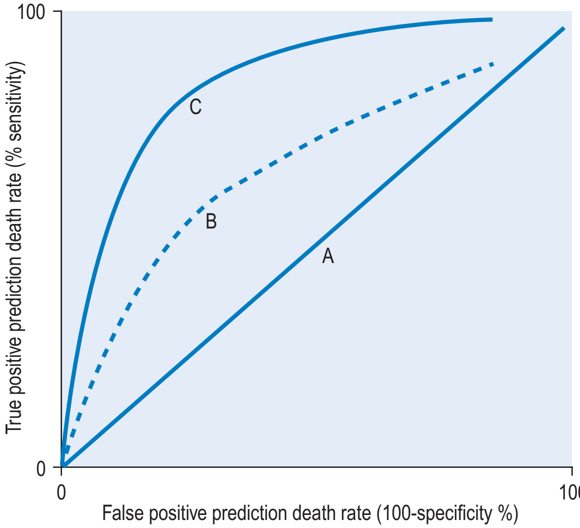

Figure 3.1 A receiver operator curve (ROC) plots true-positive against false-positive rates for a series of cut-off points for risk of death. As sensitivity or true positives increase there is a tendency for more false-positive results. There is a trade-off in making a test or predictor tool very sensitive because it loses specificity. The best curve is one that is above the line of no discrimination (A) and tends towards the *y*-axis. Therefore the model represented by line C is better than model B. The curve is made up of a series of sensitivity and false-positive estimates based on changing the threshold decision cut-offs. Typically the thresholds would be between 10 and 90% (i.e. when set at 10% the model predicts that every patient above a 10% risk of death will die). This level of cut-off will find every single death, but unfortunately there will be many false positives. This would provide a point towards the right-hand corner of the graph. When the cut-off point is made very high, such as 90%, the model will find only some of the true deaths, but there is less likelihood of a false positive and this will provide a point towards the origin of the graph closely applied to the *y*-axis.

The curve can be quantified by the area under the curve with higher values indicating more discriminatory power. For binary outcomes such as death and survival the area under the curve expressed as a fraction is the same as the concordance statistic, which varies between 0.5 and 1.

Conversely a curve that demonstrated no ability to discriminate between survivors and non-survivors would be represented by a line at 45 degrees going through the origin (non-discriminator line). The further the ROC is above the non-discriminator line and towards the *y*-axis the greater is the model's power of discrimination. This can be quantified by the c-statistic, which is a rank order statistic, or quantified by the area under the curve. The two measures are synonymous when the discrimination is between two mutually exclusive outcomes such as survival and non-survival. Prediction models that have AUC 0.7–0.8 are considered fair, those with AUC 0.8–0.9 are good, while those above 0.9 are considered excellent.

It is also possible to calculate the misclassification rate (patients predicted to die who survived and those predicted to survive who died). For example, in the APACHE II system the misclassification rates were 14.5, 15.2, 16.7 and 18.5% respectively at 50, 70, 80 and 90% predicted risk of death cut-off points, indicating that the best trade-off point between sensitivity and specificity with this model was when it was assumed that any patient with a risk of death greater than 50% would be a non-survivor. The calculations of sensitivity, specificity and misclassification rates are outlined in the (**Box 3.1**). **Table 3.2** indicates the AUC for the commonly used scoring systems.

CALIBRATION

A model with good calibration is one that for a given cohort predicts a similar overall percentage mortality to that observed. The extent to which this is achieved can be explored with the Hosmer–Lemeshow goodness-of-fit c-statistic. This compares the model's prediction of death and the actual outcome. The model is deemed to fit well and be well calibrated when there is no statistical difference between the two (i.e. the *p* value is larger than 0.05).[34]

Observations with many models have revealed that, unless the case-mix of the test patients is similar to those that were used to develop the model, the models may underperform owing to poor calibration. This is particularly true when the testing is done for patients in different countries.[16,35–37]

COMMONLY USED SCORING SYSTEMS

ACUTE PHYSIOLOGY AGE AND CHRONIC HEALTH EVALUATION (APACHE) SYSTEMS I, II, III, IV

In 1981 Knaus described APACHE, a physiologically based classification system for measuring severity of illness in groups of critically ill patients.[32] They suggested that it could be used to control for case-mix, compare outcomes, evaluate new therapies, and study the utilisation of ICUs. APACHE II, a simplified version,

Box 3.1 Calculations of sensitivity and specificity for a prediction model for mortality

When a model is tested against a cohort of patients its ability to correctly discriminate between predicted survivors and non-survivors is a measure of its power and ultimate usefulness.

Based on the data below a number of measures can be determined.

	OBSERVED DEATHS	OBSERVED SURVIVORS	TOTAL
Predicted deaths	450	100	550
Predicted survivors	40	410	450
Total	490	510	1000

Sensitivity: the proportion of observed deaths correctly predicted to die (true positive).
Sensitivity = 450/490 = 0.92.
Specificity: the proportion of survivors correctly predicted to survive (true negative).
Specificity = 410/510 = 0.80.
1 − specificity is the proportion of survivors that were predicted to be dead (false positive).
Positive predictive value: observed predicted deaths as a proportion of the total predicted deaths = 450/550 = 0.82.
Negative predictive value: observed predicted survivors as a proportion of the total predicted to survive = 410/450 = 0.91.
Misclassification rate is the proportion of patients wrongly predicted: (100+40)/1000 = 14%.
Correct classification rate is the proportion of patients correctly predicted: (450+410)/1000 = 86%.
False-positive rate = 100% − positive predictive value = 18%.
False-negative rate = 100% − negative predictive value = 9%.
Prevalence of death = 490/1000 = 49%.

Table 3.2 AUCs for commonly used scoring systems

SCORE	AREA UNDER ROC CURVE
APACHE II	0.85
APACHE III	0.90
SAPS II	0.86
MPM II_0	0.82
$MPMII_{24}$	0.84
SAPS III	0.84
APACHE IV	0.88
ICNARC 2007	0.87
MPM_0III	0.82

In effect these models are only powerful enough to discriminate between likely survivors and non-survivors between 80 and 90% of the time.

was introduced in 1985, which was superseded in 1991 by a proprietary version, APACHE III.[32,38] APACHE IV was introduced in 2006, but remains a proprietary system.[18] APACHE II rather than the later versions has become the most widely studied and used system worldwide for reporting severity of illness.

APACHE II was developed and validated on 5030 ICU patients (excluding coronary bypass patients). The score is the sum of three components:

- an acute physiology score (APS)
- a chronic health score based on defined premorbid states
- a score based on the patient's age.

The 12 variables of the APS and their relative weights were decided by expert opinion. These variables are collected in the first 24 hours after admission to ICU and should represent the worst physiological values. The APACHE II score can be included in a logistic regression equation with a coefficient for one of 50 diagnostic categories representing the reason for admission and a coefficient for admission following emergency surgery. The equation will calculate a probability of death. The probability of death, although calculated for each single individual, will only approximate the model's claimed calibration when a large cohort of patients with the same diagnostic grouping is examined (groups of at least 50). Furthermore, as in all prediction models, although the number of deaths might be predicted correctly, discriminating those who will die from those who will survive will be fraught by misclassification errors and therefore the prediction remains a probability with a defined error and cannot be used for decision making.

APACHE II has functioned best when the ICU patient cohort under test is similar to the original North American development database. The system is now old and overestimates mortality predictions, mainly because critical care management and organisation have improved significantly over the last 30 years. However, simply modifying an old scoring system does not readily correct the calibration problems, hence the need to upgrade the system using recent databases.

APACHE III was introduced in 1991 and was designed to:

- improve prognostic estimates by re-evaluating the selection and weighting of physiological variables with an expanded reference database
- examine how outcome is related to patient selection for ICU admission and its timing
- attempt individual estimates of mortality.

APACHE III was based on a large database (17 440 patients) from 40 US hospitals that was equally divided between developmental and validation groups.

Patients who were admitted for less than 4 hours, with burn injuries or with chest pain were excluded. Coronary artery bypass patients were considered as a separate group.

A total of 17 physiological variables, including a revised version of the Glasgow Coma Scale, were identified through statistical analysis and the diagnostic categories were increased from 50 to 78. The patient location immediately prior to ICU admission was included and only those co-morbidities that affected a patient's immune status were considered. Chronic disease states and age contributed 15% of the calculated mortality risk, the rest being based on the acute physiology disturbance.

APACHE III represented an advance over APACHE II with improved discriminatory power (ROC 0.9 vs 0.85), and better calibration.[38] In an early comparative study, Castella et al reported that, although APACHE II proved better calibrated than SAPS and MPM I in a 14 745 mixed patient cohort from European and American ICUs, APACHE III was better calibrated and more discriminating.[39]

A new characteristic introduced in the APACHE system was not only a calculated risk of death based on the first day values, but also serial calculations on subsequent days to provide an updated risk of death calculation for an individual. The coefficients for the regression equations are not in the public domain, and this has made independent assessment of the predictive aspect of the scoring system difficult.

APACHE IV

It was failure of customisation techniques with APACHE III to account for observations in subgroups that led to development of a new model. The authors of APACHE IV revealed that when APACHE III in its modified form was applied to patients collected between 2002 and 2003 calibration was poor.[18]

APACHE IV was based on a new database of 131 618 admissions from 104 US ICU in 45 hospitals. The selected hospitals had the APACHE III computerised data collection and analysis system already installed. Of the admissions, 110 558 patients had completed datasets and 60% were randomly selected to make up the developmental dataset. The exclusions included patients who were in hospital for more than a year or admitted from another ICU. Only first admissions were counted. The diagnostic groups were increased to 116 and not only was the location prior to admission included but also the hospital length of stay prior to ICU. The statistical and modelling techniques included cubic regression splines, which allow for a non-linear relationship between variables and outcome.

The AUC ROC derived from the model used on a validation dataset was 0.88, indicating very good discrimination. The relative contribution of the predictor variables for estimating hospital mortality is shown in **Table 3.3**.

The APACHE IV system has not been tested outside the US and therefore how it calibrates in the rest of the world is unknown. Indeed this might also be the case in the US given the selected units used for the database.[40]

Table 3.3 The relative contribution of the predictor variables for estimating hospital mortality in APACHE IV

Acute physiology	65.5%
Diagnosis	16.5%
Age	9.4%
Chronic health	5.0%
Admission source and previous length of stay	2.9%
Mechanical ventilation	0.6%

SIMPLIFIED ACUTE PHYSIOLOGY SCORE (SAPS I–III)

The Simplified Acute Physiology Score (SAPS) was originally based on data derived from French ICU, and based almost entirely on acute physiological variables.[9] The chosen 14 physiological variables were selected by experts and arbitrary scores were based on the degree of deviation from normal. Initially the score was not related to an equation for predicting probability of death, although later this was possible. Unlike APACHE II this system included neither diagnostic categories nor chronic health status as part of the severity of illness estimate.

In 1993 SAPS II was introduced and this was based on European and North American patients.[41] The database contained 13 152 patients, divided 65% and 35% between developmental and validation cohorts. Excluded patients included those under 18 years, with burns, receiving coronary care or post cardiac surgery.

The weightings given to physiological derangements were derived from logistic regression analysis. The variables included 12 physiological measurements and specific chronic health conditions such as the presence of AIDS, haematological malignancies, cirrhosis and metastasis. Like the original SAPS there was no requirement for inclusion of diagnostic groups. The probability for hospital death could be readily calculated from a logistic regression equation. In the validation sample the area under the ROC was 0.86 with equivalent calibration and discrimination to APACHE III and MPM II. It is the most commonly used scoring system in continental Europe.

SAPS III

SAPS III was introduced in 2005 and developed from a database of 16 784 patients from 303 ICU from around the world including South and Central America.[15,16] The model used multilevel logistic regression equations based on 20 variables.

The authors separated variables into those related to the period prior to admission, those concerning the admission itself and those of the acute physiological derangement (**Table 3.4**).

The SAPS III score can be used to derive a risk of death from a logistic regression equation. Discrimination was

Table 3.4 Factors considered in SAPS III

PATIENT CHARACTERISTICS BEFORE ADMISSION	CIRCUMSTANCES SURROUNDING ADMISSION	ACUTE PHYSIOLOGICAL CHANGES WITHIN 1 HOUR BEFORE AND AFTER ADMISSION
Age	Planned or unplanned	GCS
Comorbidities	Reason for admission (diagnostic group)	Bilirubin
Length of stay before ICU admission	Medical or surgical	Temperature
Hospital location before admission	Anatomical site of surgery	Creatinine
Vasoactive agents before admission	Acute infection at time surgery	Leucocytes pH Systolic BP Oxygenation and mechanical ventilation

good, with ROC AUC 0.848. The calibration varied, however, depending on the geographical area tested. The best fits for the general SAPS III risk adjustment model were for Northern European patients while the worst was for Central and South America. This simply reflected the lower number of patients from those areas in the developmental dataset. However, the model can be customised with alternative equations to improve calibration for different regions of the world.

The authors found that 50% of the model's explanatory power for predicting hospital mortality was from patient characteristics prior to admission, while circumstances surrounding admission and acute physiology parameters accounted for 22.5 and 27.5% respectively. The lower explanatory power compared with APACHE IV is notable and may be due to the absence of diagnostic weights in SAPS III.

MORTALITY PREDICTION MODELS (MPM I–III)

MPM was introduced in 1985 to provide an evidence-based approach to constructing a scoring system.[42] The data were derived from a single US institution and included observations at the time of admission to ICU and within the first 24 hours. MPM I_0 was based on the absence or presence of some physiological and diagnostic features at the time of admission, while a further prediction model MPM I_{24} was based on variables reflecting the effects of treatment at the end of the first ICU day. Unlike APACHE and SAPS systems it does not calculate a score based on the extent of physiological derangement, but computes the hospital risk of death from a logistic regression equation from coefficients based on the presence or absence of 15 factors such as coma, chronic renal failure, cirrhosis, heart rate over 150, systolic blood pressure below 90 mmHg (≈12 kPa) and several others.

MPM II is based on the same dataset as SAPS II.[33] The system is a series of four models which provide an outcome prediction estimate for ICU patients at admission and at 24, 48 and 72 hours. In common with the early APACHE and SAPS systems, the models excluded burns, coronary care and cardiac surgery patients. The models were derived by using logistic regression techniques to choose and weight the variables with an additional criterion that variables had to be 'clinically plausible'.

MPM_0 and $MPMII_{24}$ have similar discriminatory power to SAPS II, with ROC AUCs of 0.82 and 0.84 respectively.

In a comparison between MPM II, SAPS II and APACHE III and the earlier versions of these systems, all the newer systems performed better than their respective older versions; however, no system stood out as being superior to the others.[39]

In 2007 MPM_0III was introduced because it was noted that MPM II had lost its calibration against patients who were being recruited into the ongoing Project IMPACT.[43] This was probably due to changes in practice rather than case-mix. MPM_0III was based on retrospective data from 135 ICUs and 124 855 patients collected between 2001 and 2004. The patients were randomly divided into development (60%) and validation (40%) sets. The same variables as MPM II were collected, but included whether the patient was 'do not attempt resuscitation' at the time of admission (1 hour before or after admission). The resulting statistical analysis revealed that not only were the same variables retained but also there was a need to include interactions between age and each of the variables of systolic pressure, cirrhosis, metastatic neoplasms, cardiac dysrhythmia, intracranial mass effect and CPR prior to admission in order to correct overprediction of mortality. The authors achieved better calibration with MPM_0III than with their earlier model. The strengths of the MPM systems are that the burdens of data collection are low and the variables are boolean. The data are collected at the time of admission. This simplicity of collecting fewer variables at admission unfortunately has a trade-off in that discriminatory power is lost compared with other models. However, discriminatory power with ROC AUC at 0.82 remains acceptable.

ICNARC MODELS

ICNARC (Intensive Care National Audit and Research Centre) is a UK organisation dedicated to the collection and analysis of critical care data derived from over 160 ICU on a regular basis. It initially collected data for SAPS, APACHE II and MPM, and in the APACHE II model replaced the original diagnostic categories with its own to improve calibration for the UK. Its success has been based on a consistent methodology for data collection and therefore year-on-year data can be used to update diagnostic coefficients for APACHE II to ensure contemporary calibration. Furthermore, confidence in the data has allowed development of its own ICNARC mortality prediction model. The current ICNARC model was introduced in 2007 and upgraded with new coefficients in 2011. The model was originally based on 163 general ICUs using data collected between 1995 and 2003.[11] The model ultimately included data from 216 626 patients. Re-admissions during the same hospital spell were not included. This model was also based on logistic regression analysis and isolated 12 physiological variables, which if all at their worst added up to a score of 100. The model also included age, diagnostic categories, source of admission and whether a patient had received CPR prior to admission. The model showed a high degree of discrimination (0.874) and calibration when applied to a validation set. Interestingly the impact of chronic health was found to be less than expected. Its weakness like the APACHE system is that it is entirely based on a national cohort and may not be suitable outside the UK.

ORGAN FAILURE SCORES

It is intuitive that as more organs fail the likelihood of death increases. As part of his work with APACHE, Knaus devised a simple predictive table in which, depending on age, the number of organs failed and the duration of failure he could estimate the likely risk of death. The organ system failures (OSFs) were defined for 5 organs.[44]

The notable observations were that:

- a single OSF lasting more than 1 day resulted in a hospital mortality rate of 40%
- two OSFs for more than 1 day increased rates to 60%
- three or more OSFs lasting more than 3 days were associated with a mortality of 98%.

Advanced chronological age increased both the probability of developing OSF and the probability of death once OSF occurred. These figures probably overestimate the risk of death in most parts of the world today.

Scores have been described that take account of grades of dysfunction and the supportive therapy required. One of these is the Multiple Organ Dysfunction Score (MODS), which was based on specific descriptors in six organ systems (respiratory, renal, neurological, haematological, cardiovascular and hepatic). Progressive organ dysfunction was measured on a scale of 0 to 4; the intervals were statistically determined for each organ based on associated mortality. The summed score (maximum 24) on the first day score was correlated with mortality in a graduated fashion.[45]

In this organ failure system the ICU mortality was approximately:

- 25% at 9–12 points
- 50% at 13–16 points
- 75% at 17–20 points
- 100% at levels of >20 points.

The score demonstrated good discrimination with areas under the ROC of 0.936 in the development set and 0.928 in the validation set.

Another organ failure score that is commonly used is the Sequential Organ Failure Assessment (SOFA). This score was originally constructed to provide a simple score for daily organ dysfunction in sepsis trials. Subsequently the 'sepsis' in SOFA was renamed 'sequential' to broaden its use. It takes into account six organs (brain, cardiovascular, coagulation, renal, hepatic, respiratory) and scores function from 0 (normal) to 4 (extremely abnormal). Experts defined the parameter intervals.[46] It has the merit of including supportive therapy and, although increasing scores can be shown to be associated with increasing mortality, it was not designed for estimation of outcome probability.

Around the same time as the introduction of SOFA the more scientifically based LODS (Logistic Organ Dysfunction Score) was also described. LODS is an organ failure score that could be used for hospital outcome prediction.[47] It was based on the first-day data of patients who made up the SAPS II and MPM II developmental cohort. The LODS system identified up to three levels of organ dysfunction for six organ systems. Between 1 and 5 LODS points were assigned to the levels of dysfunction. The resulting total LODS scores ranged from 0 to 22 points. Calibration and discrimination were good. It demonstrated that neurological, cardiovascular and renal dysfunction carried the most weight for predictive purposes whereas pulmonary, haematological and hepatic dysfunction carried the least. Unlike SOFA it weights the severity of illness between organs and the degree of severity within an organ system.

SCORES FOR INJURY AND TRAUMA

Patients who suffer physical injury are a relatively homogeneous group, which facilitates categorisation of their illness severity on anatomical damage (Injury Severity Score, ISS) and/or disturbance of vital physiology (Revised Trauma Score, RTS).

ISS is based on the Abbreviated Injury Scale (AIS), which is a consensus-derived anatomically based method for ranking injury for six body regions (head and neck, abdomen, pelvis contents, face, chest and

body surface). Unlike the physiologically based general severity of illness scores, which use data at the height of acuity, ISS is anatomical and therefore any injury no matter when detected is relevant; hence data obtained from post-mortem evidence are included.

The first AIS was published in 1969 by the Society of Automotive Engineers.[48] The original reason was to provide standardisation for degree of injury for motor vehicle crash investigators to inform vehicle design. Subsequently other organisations became interested, namely the American Medical Association, and Association for the Advancement of Automotive Medicine. The latter has since taken the lead in updating AIS with major changes in 1976, 1980, 1985, 1990, 1998, 2005 and 2008. The changes have been recoding and alteration of the values for injury.[49,50] AIS values range from 1 (minor) to 6 (untreatable).[49,50] ISS is calculated from the sum of the squares of the highest AIS score (1–5 excluding 6 the non-survivable score) in the three most severely injured body regions. Baker noted that an injury in a second and third region, even if minor, significantly increased mortality; additionally it was observed that the sum of the squares of each score was more linearly related to mortality than the sum of individual scores.[51] The highest score in each body region is 5 and consequently the highest ISS is 75. However, the sum of squares means that certain scores such as 7 and 15 will never be obtained, whereas numbers such as 9 and 16 will be common. This means that statistical analysis should avoid parametric tests on the scores.

Major trauma is defined as an ISS greater than 15 and is associated with a greater than 10% risk of mortality. However, ISS is a purely anatomical system and ignores physiological derangements or chronic health status, this reduces its usefulness for predicting the outcome of cohorts. Care should also be taken when using ISS to compare data year on year if the ISS calculation has been based on different versions of AIS.[52]

A modification of the ISS, the New Injury Severity Score (NISS) has been suggested and considered a better model relating AIS to outcome.[53,54] NISS, unlike ISS, uses the three highest AIS scores even if they are in the same anatomical region, because it was felt that ISS would underestimate the effect on outcome of two very severe injuries in one body region. NISS has been adopted as the standard by the EuroTarn (Trauma audit and research network) project, which aims to establish a consistent dataset and registry for data collection and outcome comparisons in Europe.

The Trauma Score (TS) was introduced as a physiologically based triage tool for use in the field, based on systolic blood pressure, capillary refill, respiratory rate, chest expansion and the Glasgow Coma Scale (GCS). It was suggested along with age to compliment the anatomical scores derived from AIS.[55] However, incorporation of the TS was later reviewed owing to the difficulties of assessing capillary refill and chest expansion in the field and modified to the Revised Trauma Score (RTS).[56]

RTS is based on disturbances in three variables, each coded between 1 and 4:

- GCS
- systolic blood pressure (BP)
- respiratory rate.

Individually, both ISS and RTS had flaws as predictors of outcome from trauma. Boyd imaginatively combined these physiological and anatomical measures with coefficients to provide the Trauma Injury Severity Score (TRISS) methodology for outcome prediction.[57] TRISS, which was developed from the data of 30 000 injured patients, included the presence of penetrating injury and age in its methodology for outcome prediction.[51,56,57] Like other scoring systems it facilitates comparisons between trauma centres and year on year within centres by using expected and observed outcomes. However, because it uses the standard ISS rather than NISS, TRISS is exposed to the same tendency to underestimate the impact of more than one severe injury in the same anatomical region and risks poor calibration.[58–61] TRISS was found to be no better than APACHE II for the patients requiring ICU admission.[62] Also, as might be expected with improvements in trauma care, the TRISS coefficients have become progressively misaligned so that the original model has become less well calibrated.[63,64]

ASCOT (A Severity Characterization Of Trauma) was introduced to rectify perceived problems with TRISS.[65] There are more details on injuries in the same body region, more age subdivisions and the use of emergency room acute physiology details rather than field values. ASCOT predicted survival better than TRISS, particularly for blunt injury. However, there has been reluctance to use ASCOT owing to its increased complexity for only a modest gain in predictive value.

APPLICATION OF SCORING SYSTEMS

Since their introduction, scoring systems for general ICU patients have acquired a more defined role. Having originally been considered a method for quantifying risk of death and potentially managing ICU resources, they have found a more comfortable niche as the accepted tool for benchmarking research trials where case-mix is often similar in the control and active treatment groups. For an individual ICU the Standardized Mortality Ratio (SMR), which compares the observed hospital outcome with the expected one, is a useful measure. It is particularly helpful when used year on year to follow progress in quality of care. Even if a unit is poorly calibrated nationally, longitudinal within-unit performance comparisons remain valid assuming a wonder drug or treatment has not intervened and the case-mix has remained unchanged.

Traditionally SMR values of 1 indicate expected performance, whereas values below 1 and above 1 indicate respectively better and worse performances than expected.

SMR values, which are surrogates for quality of care, have to be used with caution when comparisons are made between intensive care units. A case-mix that deviates from the original developmental case-mix can cause anomalies and variance in calibration from one unit to another.[37]

When calibration is not a cause for concern it still remains difficult to quantify whether a SMR of 1 is significantly worse than one of 0.8. This assessment would have to take account of the standard deviations around the logistic regression equations. As a rule it is wise to avoid comparisons unless samples are very large and with a similar distribution of similar case-mix.

Scoring systems have also been used to explore the association between nursing resource needs and acuity at presentation, however assessing nurse:patient ratios might be more simply based on organ support requirements. Scoring systems have also been used to predict length of stay and therefore estimate bed requirements.[66]

Decision making for an individual patient based on the predictions of scoring systems is universally considered inappropriate because these systems are unable to discriminate with certainty and have misclassification rates in excess of 15%.[14,32,67,68] The logistic regression equations derived from large cohorts of mixed populations provide a probability for the dichotomous events of death or survival and therefore they have no potential use as a guide to further treatment or limitation orders for an individual.

While there are always attempts to correct for calibration and discrimination through new coefficients or new databases, the closest one can get to providing a system for individual prediction is through on-going recalibration with neural networks. Simplistically these systems use patient data feeding back to continually modify predictor equations. This approach theoretically gets closer and closer to predicting outcome, but it never reaches certainty.

Although it is important to recognise the hopelessly ill patient as early as possible, it is likely that management decisions will remain firmly based on clinical judgement rather than scores for the foreseeable future.

Transport of critically ill patients

Evan R Everest and Matthew R Hooper

Critical illness and injury are not necessarily defined by patient location. In addition, patients may overwhelm the level of care at their current location or require specific investigations or treatments not immediately available to them. For this reason, transport of critically ill and injured patients occurs frequently.

Critical care patient transport has traditionally been divided into two groups; patient movement within a hospital (intra-hospital) or movement between hospitals (inter-hospital or inter-facility). In addition, a select group of critically ill or injured patients not located in a hospital facility may be managed by physician-based medical teams prior to retrieval to a medical facility. Therefore, a third division (primary response or pre-hospital care) is well recognised.

The internationally widespread deployment of medical teams for critically ill patient management and retrieval from both health care facilities and pre-hospital locations has resulted in the developing recognition of pre-hospital and retrieval medicine as a distinct subspecialty.[1]

INTRA-HOSPITAL TRANSPORT

Transports are usually required to facilitate critical investigations and interventions or to move the patient from one critical care area to another. Critically ill or injured patients with limited or no physiological reserve undergoing such transports are at risk of clinical deterioration and adverse events are well reported.[2,3] In order to reduce the mortality and morbidity associated with patient movement, a structured approach utilising high-level clinical personnel who have the correct equipment, training and sufficient planning time is required.

Moving the patient should be associated with little or no compromise in their condition. Unfortunately this is not the case with an adverse event occurring in up to 70% of transports. One-third of these events are equipment related,[4] whereas deterioration in gas exchange[5] and increased rates of ventilator-associated pneumonia are common.[6] However, management is changed in 40–50% of patients, thus justifying the risk.

Patients with unstable physiology should not be transported for non-urgent interventions or investigations. However, where the intervention or investigation is deemed critical to achieving patient stability or providing definitive management, the benefits in patient outcome will outweigh the inherent risks of transport. The transport can therefore be seen as part of the patient's therapeutic requirement and stabilisation process. On occasions when the patient's need is so acute and/or the likelihood of irreversible deterioration in transit is so high consideration should be given to facilitating such interventions or investigations in the ICU rather than the locality where these procedures would normally occur.

When preparing for intra-hospital transport, the following structured approach is recommended:

- Clinical reassessment should occur swiftly, systematically and, whenever possible, with the patient already supported on the equipment that will be used during transport.
- The airway should be checked and secured, endotracheal suction performed, ventilation and oxygenation optimised, adequate and patent vascular access secured and drainage devices measured and emptied.
- Sedation and analgesic requirements should be addressed and any drugs required for transport (including additional infused agents) pre-drawn and labelled for immediate use.
- Ensure that the patient clinical record remains with the team caring for the patient.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING SCANNING

CT scanning is the most common ICU diagnostic intervention requiring patient movement. Head injury patients and those requiring previous administration of oral contrast with decreased gut motility (and thus increasing risk of aspiration) require extra attention. The administration of i.v. contrast through standard multi-lumen central lines is not possible and a large-bore intravenous cannula needs to be inserted and well secured prior to leaving the ICU. Single-lumen large-bore central catheters are an alternative but should be used only as a last resort.

Repeated CT scanning of head-injured patients is common. In these patients with decreased cerebral

compliance, movement or changes in body position or Pa_{CO_2} can result in significant elevations in intracranial pressure. Although movement-induced changes in ICP can be reduced with sedation, very little can be done about body position. Changes in Pa_{CO_2} are usually due to variation between ICU and transport ventilators. Most transport ventilators are less precise at setting tidal volume, respiratory rate and PEEP compared with standard ICU ventilators. These changes can have significant effects on minute volume and lung compliance. If time permits, Et_{CO_2} should be established using the transport monitor for 10–15 minutes. This sets the baseline Et_{CO_2} that must be maintained when the patient is connected to the transport ventilator. Respiratory rate or tidal volume is adjusted to maintain the Et_{CO_2}. Ideally the ICP should also be measured but at times this may not be possible.

Radiation exposure for both the patient and staff needs to be considered. A stable patient who is adequately monitored with alarms activated can be observed by staff outside the room. The patient should be moved back to the ICU as soon as scanning is completed.

The use of MRI for ICU is increasing as a diagnostic and prognostic tool for a wide range of ICU patients. The major problems with MRI are the effect that the magnetic field may have on ventilators, monitors and infusion pumps and the potential for these items to become effectively a missile by being attracted to the magnet. The last 5–10 years have seen the development of monitoring and ventilators that are MRI compatible and the acceptance of standards for equipment in the MRI. These magnetic resonance standards are: MR safe, conditional or unsafe. Safe and unsafe are self-explanatory, while conditional relates to equipment that is safe when kept at a predetermined distance from the magnet. Although a lot of equipment has been developed as MR safe, it has been developed from anaesthetic practice for the provision of general anaesthesia during the MRI examination for some patients. This equipment is 'foreign' to most ICU staff and often is not used owing to lack of familiarity. As a result there has been a blending of practice: using some of the 'anaesthesia' equipment but also continuing to use ICU infusions and ventilators at some distance from the magnet. Distance from the magnet is achieved by the insertion of extension tubing but this must be balanced with the risk of disconnection.

Thermal dilution pulmonary artery catheters are probably safe, although opinion varies. Absolute contraindications for MRI scanning include pacemakers, internal defibrillators and cerebral aneurysm clips, whereas other clips may require a period of time, up to 6 weeks, to allow stabilisation within the tissues before scanning can occur. Prior discussion with the MRI unit must occur before the patient is moved from the ICU. Most MRI units will require an MRI checklist to be completed prior to scanning.

STAFFING

A team consisting of at least one ICU medical officer and nurse should be free from other duties. Both team members should be thoroughly familiar with the transport process, equipment and environment. The team should possess the requisite skills and knowledge to independently manage critically ill patients in transit and to deal with anticipated emergencies. The more complex and unstable the patient is, the more capable the team must be. For very unstable patients an additional nurse and more senior doctors may be required. Assistance with safe patient, trolley and equipment movement will also be needed. Non-clinical hospital support staff are therefore part of the team and should be included in all briefs and contingency planning.

EQUIPMENT

Transport equipment should be regularly checked and serviceable. Powered devices should be fully charged, with power cords accessible to facilitate use of mains power in the event of delay. Where possible, equipment should be lightweight, robust and standardised throughout the ICU and hospital. In transit, equipment should be secured (not resting on the patient) but readily accessible. Dedicated transport bridges or gantries are commonly used. Dedicated transport packs or boxes ensure safe carriage of consumable items, resuscitation equipment and drugs. Equipment required for emergency airway management (e.g. bag valve mask, laryngoscope, airway devices and endotracheal tubes) should be immediately available.

MONITORING

As a minimum, intubated and ventilated patients requiring intra-hospital transport should have the following monitoring instituted:[7]

- continuous Et_{CO_2}
- continuous Sa_{O_2}
- continuous invasive or intermittent non-invasive BP
- continuous three-lead ECG.

Ideally, a cardiac monitoring device should also provide cardiac defibrillation and external cardiac-pacing capacity. Patients requiring transport with more advanced monitoring in situ should be considered on a case-by-case basis. For example, ongoing ICP monitoring is critical to ensure avoidance of profound unmonitored falls in cerebral perfusion pressure in an ICU patient with a severe head injury, whereas pulmonary artery pressure monitoring may be excluded from the transport requirements in the haemodynamically stable patient.

INTER-HOSPITAL TRANSPORT

Historical models of inter-hospital patient transfer utilising junior medical staff as 'patient escorts' have much

higher rates of hypotension, acidosis and death.[8] Thankfully this type of transport has become increasingly rare with the introduction of specialist retrieval services.

The general principles of patient transport, irrespective of the physical location of the patient, regarding equipment, patient monitoring and clinical requirements remain the same. Standards for transportation of the critically ill have been widely promulgated and must be followed whether it is a complex unstable patient being moved long distances or a semi-elective CT in a stable ICU patient.

With rising expectations for high-level care by the community in both metropolitan and rural locations and with the care for critically ill and injured patients becoming increasingly centralised in large, tertiary, metropolitan ICUs, the need to transfer patients between health care facilities has also increased. Such a demand has seen the development of dedicated specialist retrieval teams. These teams are trained to manage patients in the inter-hospital environment and have varied professional backgrounds. Although these teams can deal with most inter-hospital transfers there are a number where the patient complexity may be beyond the standard retrieval team and additional clinical personnel need to be added for the patient transfer. Inter-hospital transfer of a patient on ECMO (see below) is an example where a complex patient is being managed by a highly specialised team with little or no experience of moving patients in the inter-hospital environment. In these relatively rare cases the role of the retrieval team is to assist by providing the logistical and inter-hospital expertise to allow the ECMO team to concentrate on caring for the patient.

RETRIEVAL CLINICAL COORDINATION AND ADVICE

Retrieval clinical coordination describes the process whereby specialist medical, nursing, paramedic and ambulance service staff are involved in direct supervision of the primary and inter-hospital transport or retrieval of patients. This is to ensure the:

- safe and efficient use of expensive transport and retrieval services
- high-level clinical advice is available prior to and during transport
- the patient is delivered in a timely manner to the most appropriate receiving hospital

safe and efficient use of expensive transport and retrieval services, that high-level clinical advice is available prior to and during transport, and that the patient is directed in a timely manner to the most appropriate receiving facility.

Not all patients who are referred for retrieval will require transport. Of those who do, not all will require emergency retrieval and not all will require a retrieval team. To ensure that this is addressed, an integrated systems approach is required. In general a retrieval service will be used when the complexity of the patient exceeds the ambulance service's ability to transport the patient. Patients requiring a retrieval response may be identified by:

- a diagnosis with the potential to deteriorate
- a clinical requirement for invasive physiological monitoring or acute intervention
- to facilitate continuity of already instituted critical care supports.

Tele-medicine is playing an important and increasing role in this process – not only in assisting decision making regarding retrieval activities (resulting in potential cost savings), but also in supporting remote and regional medical practitioners faced with acutely ill or injured patients and in supporting a retrieval team before and during patient transport.

When there is a requirement for a rapid medical response to a time-critical pre-hospital or retrieval incident, a retrieval service must be able to be activated swiftly and in a coordinated approach with other emergency services. For this reason, many retrieval coordination centres are co-located with ambulance service communication centres. In this way, clinical and logistic expertise is integrated.

Retrieval coordination centres should ideally be accessed by a single number and provide early teleconferencing of the referral agency, a senior critical care clinician (such as a receiving intensive care specialist, relevant specialist clinician or medical retrieval specialist), and occasionally the retrieval team.

Knowing where key assets (transport platforms such as road ambulances, helicopters and fixed wing aircraft) and retrieval teams are at any one time is crucial to effective retrieval clinical coordination. Real-time asset tracking or mapping systems and advanced radio or phone communication networks assist in this regard.

RETRIEVAL TEAM STAFFING

The aim of the team is to at least maintain, but ideally to increase the level of care during transport. This requires a team of sufficient size and skill to provide the full complement of care for the majority of patients being transported.

The minimum team should comprise two people; occasionally a very-low-acuity stable patient may be escorted by a single person. If multiple patients are to be transported a recommended staffing level is $n+1$ where n equals the number of patients.[10]

Who makes up the team continues to be debated. In most cases a doctor will be one member while the other can be a person with either acute care nursing or ambulance background. For a primary pre-hospital response, the combination of a doctor and paramedic is the best mix; the paramedic is familiar with the pre-hospital scene environment and can often guide and

support a doctor, especially one early in their retrieval career, while a doctor/nurse combination may be appropriate for complex inter-hospital transfers. The future second person will potentially be someone who has both an acute care nursing and paramedic background and will feel comfortable operating in both environments. Other requirements include the ability to work and communicate as a team, have reasonable body habitus and physical fitness and have no visual or auditory impairment or a susceptibility to motion sickness. In aviation transport the weight of the teams and their equipment is important as there is a maximum weight available. High team weights can limit the amount of fuel able to be carried, which may compromise some missions.

As discussed above there will be some highly complex cases that may be outside of the team's capability and supplementation of the retrieval team by additional specialist personnel may be required. An example of obstetricians or neurosurgeons[11] depending on the type of mission may be added. It is mandatory that the specialist is added to a standard team because of the latter's familiarity with working in the retrieval environment.

TRAINING

Training should cover the following:

- standard operating procedures for the service
- the use of scenarios to teach common procedures and also principles
- familiarity in the various transport platforms to be used; this would include safety briefings on aerial assets and may include helicopter underwater escape training (HUET) and crew (cockpit) resource management (CRM)
- communication procedures
- understanding of the effects of altitude and flight on patient (and team) physiology.

EQUIPMENT

GENERAL CONSIDERATIONS

Minimum equipment standards for supplies, equipment and monitoring have been published.[7] The equipment carried is often a compromise between providing for every conceivable situation and lightweight and mobile. In some cases it is appropriate to have additional or procedure packs that are taken only when warranted by the clinical situation; for example, a Sengstaken–Blakemore tube or temporary transvenous pacing wire is taken only when a GI haemorrhage occurs in a patient who might have varices or the patient has symptomatic complete heart block. This requires a good communication and coordination process.

A suggested list of equipment is given in **Box 4.1**.

Transport monitors, infusion pumps and ventilators must work out of the transport vehicle. They must be battery powered whilst ideally allowing for utilisation of ambulance or aircraft power during transport. Batteries in most modern systems are either sealed lead acid or lithium. There is no place for the older-style Nicad battery, which needs to be totally discharged prior to recharging to overcome memory effect. Battery life is quoted for new batteries and with time this value decreases. Planning on a battery life of 50% of that quoted is prudent. Spare batteries can be carried but changing them usually result in temporary interruption of monitoring. With the newer, smaller defibrillators at least one spare battery is essential. During transport the equipment must be securely stowed. There are international standards in the 'G force' that securing systems must withstand in the event of a crash. In some modern road vehicles or helicopters the requirement is 20 G. The use of a suitability engineered 'stretcher bridge' attached to the patient's stretcher and to which the equipment can be secured provides the most safety.[12]

MONITORING

Clinical observation by experienced clinicians remains an important facet of monitoring.[13] However, there are significant limitations to this approach. It is difficult to auscultate adequately in a moving vehicle and impossible in a helicopter. As a minimum, ECG, pulse oximetry and non-invasive blood pressure (BP) measurement must be provided with the addition of end-tidal CO_2 (Et_{CO_2}) for any intubated patient. Non-invasive BP measurements are often subject to interference, and for critically ill patients invasive arterial access is essential, especially if the length of the transport is long.[14] Newer defibrillators combine defibrillation and the monitoring aspects as outlined above may be an advantage. However, non-invasive BP and defibrillation uses a lot of battery power and spare batteries are essential or must be carried. The use of portable biochemical analysers provides additional management information in long transports.

VENTILATORS

A mechanical ventilator must be used on all intubated patients as manual ventilation cannot reliably deliver constant tidal volumes and a stable Et_{CO_2}.[15] However, a manual system must be available in the rare event of a ventilator failure. Transport ventilators are a compromise between portability and features. Over the last 5 years the desired features as listed in **Box 4.2** have almost been met apart from the ability to ventilate neonates to large adults. Small neonates still require a specific ventilator.

The provision of non-invasive ventilation (NIV) such as continuous positive airway pressure (CPAP) or BiPAP now possible on most modern transport ventilators. An improvement with inspiratory valve-triggering technology has resulted in substantial reductions in

Box 4.1 Suggested equipment schedule for inter-hospital critical care transport

Respiratory equipment

Intubation kit:
- Endotracheal tubes and connectors – adult and paediatric sizes
- Introducers, bougies, Magill forceps
- Laryngoscopes, blades, spare globes and batteries
- Ancillaries: cuff syringe and manometer, clip forceps, 'gooseneck' tubing, HME/filter(s), securing ties, lubricant

Alternative airways:
- Simple: Geudel and nasopharyngeal
- Supraglottic: laryngeal masks and/or Combitube
- Infraglottic: cricothyrotomy kit and tubes

Oxygen masks (including high Fi_{O_2} type), tubing, nebulisers

Suction equipment:
- Main suction system – usually vehicle mounted
- Spare (portable) suction – hand-, O_2-, or battery-powered
- Suction tubing, handles, catheters and spare reservoir.

Self-inflating hand ventilator, with masks and PEEP valve

Portable ventilator with disconnect and overpressure alarms

Ventilator circuit and spares

Spirometer and cuff manometer

Capnometer/capnograph

Pleural drainage equipment:
- Intercostal catheters and cannulae
- Surgical insertion kit and sutures (see below)
- Heimlich-type valves and drainage bags

Main oxygen system (usually vehicle-mounted) of adequate capacity with flowmeters and standard wall outlets

Portable/reserve oxygen system with flowmeter and std outlet

Circulatory equipment

Defibrillator/monitor/external pacemaker, with leads, electrodes and pads

IV fluid administration equipment:
- Range of fluids: isotonic crystalloid, dextrose, colloids
- High-flow and metered flow-giving sets
- IV cannulae in range of sizes: peripheral and central/long lines
- IV extension sets, 3-way taps and needle-free injection system
- Syringes, needles and drawing-up cannulae
- Skin preparation wipes, IV dressings and Band-Aid
- Pressure infusion bags (for arterial line also).

Blood pressure monitoring equipment:
- Arterial cannulae with arterial tubing and transducers
- Invasive and non-invasive (automated) BP pressure monitors
- Aneroid (non-mercury) sphygmomanometer and range of cuffs (preferably compatible with NIBP also)

Pulse oximeter, with finger and multi-site probes

Syringe/infusion pumps (minimum two) and appropriate tubing

Miscellaneous equipment

Urinary catheters and drainage/measurement bag

Gastric tubes and drainage bag.

Minor surgical kit (for ICC, CV lines, cricothyrotomy, etc.):
- Sterile instruments: scalpels, scissors, forceps, needle holders
- Suture material and needles
- Antiseptics, skin preparation packs and dressings
- Sterile gloves (various sizes); drapes +/– gowns

Cervical collars, spinal immobilisation kit, splints

Pneumatic anti-shock garment (MAST suit)

Thermometer (non-mercury) and/or temperature probe/monitor

Reflective (space) blanket and thermal insulation drapes

Bandages, tapes, heavy-duty scissors (shears)

Gloves and eye protection

Sharps and contaminated waste receptacles

Pen and folder for paperwork

Torch +/– head light

Drug/additive labels and marker pen

Nasal decongestant (for barotitis prophylaxis)

Pharmacological agents

CNS drugs:
- Narcotics +/– non-narcotic analgesics
- Anxiolytics/sedatives
- Major tranquillisers
- Anticonvulsants
- IV hypnotics/anaesthetic agents
- Antiemetics
- Local anaesthetics

Cardiovascular drugs:
- Antiarrhythmics
- Anticholinergics
- Inotropes/vasoconstrictors
- Nitrates
- Alpha and beta blockers, other hypotensives

Electrolytes and renal agents:
- Sodium bicarbonate
- Calcium (chloride)
- Magnesium
- Potassium
- Loop diuretics
- Osmotic diuretics

Endocrine and metabolic agents:
- Glucose (concentrate) +/– glucagon
- Insulin
- Steroids

Other agents:
- Neuromuscular blockers: depolarising and non-depolarising
- Anticholinesterases (neuromuscular block reversal)
- Narcotic and benzodiazepine antagonists
- Bronchodilators
- Antihistamines
- H_2 blockers/proton pump inhibitors
- Anticoagulants
- Thrombolytics
- Vitamin K
- Antibiotics
- Oxytocics
- Tocolytics
- Diluents (saline and sterile water)

Additional/optional equipment
- Portable ultrasound machine
- Transvenous temporary pacing kit and pacemaker
- Blood (usually O negative) and/or blood products
- Additional infusion pumps and associated IV sets
- Obstetrics kit
- Additional paediatric equipment (depending on capability of basic kit)
- Antivenin (polyvalent or specific)
- Specific drugs or antagonists

Box 4.2 Features of an ideal transport ventilator

- Small, light, robust, and cheap
- Not dependent on external power source
- Easy to use and clean, with foolproof assembly
- Economical on gas consumption
- Suitable for patients from neonates through to large adults
- F_{IO_2} continuously variable from ambient air to 100% oxygen
- Able to deliver PEEP, CPAP, SIMV and pressure support
- Variable I:E ratios
- Flow or pressure generator modes
- Integrated monitoring and alarm functions with audio and visual signals
- Altitude compensated

circuit work with concurrent reduction in the work of breathing. Although clapperboard CPAP systems provide the least circuit work and are optimal for patients with high work of breathing, the new transport ventilators are close enough to ideal to be used. Most patients will tolerate NIV with the modern ventilators, but it does require a different approach by retrieval teams. There needs to be a period of observation prior to transport as the ability to provide advanced airway support in transit is limited.

In most cases heat moisture exchangers (HME) will provide adequate humidification for intubated patients.

A suction system and reserve are required. In most transport vehicles this can be provided by electrically powered devices and a back up such as a gas powered venturi system as a back-up.

INFUSIONS

Critically ill patients often need multiple infusions to be continued during transport. Some drugs that ideally should be given as infusions can be consolidated by combining sedation drugs, or the infusion stopped and given instead by frequent boluses. The older-style volumetric and drop-counting pumps have been superseded by lightweight syringe drivers, which should be the only method used for drug infusions in contemporary retrieval practice.

INTRA-AORTIC BALLOON PUMP (IABP) AND EXTRACORPOREAL MEMBRANE OXYGENATION (ECMO)

Retrieval of patients with IABP in situ has been occurring for many years and, in general, a team with some experience in trouble shooting any pump alarms can manage these patients. The IABP machines are reasonably bulky and heavy with an internal battery life of 1–2 hours. The type of transport vehicle has to be considered to ensure that the pump can be safely secured and can be connected to an external power source either 12–28 V or mains power equivalent. Although the pump will run on external 12–28 V, most pumps require connection to mains power to recharge the battery, so it is essential to limit the time on internal batteries. Insertion of an IABP catheter requires some experience and some pre-departure consideration of the team's capabilities must be made. The addition of an extra doctor experienced in IABP insertion to the standard retrieval team should be considered.

The 'swine flu' epidemic in 2010 saw the rapid emergence of ECMO as a valid treatment for severe viral-induced respiratory failure.[16] It was recognised that ECMO should be provided in a relatively small number of institutions and that ideally patients likely to need ECMO should be transferred early. However, significant numbers of patients deteriorated rapidly and rescue ECMO was instituted in many non-ECMO centres, hence requiring the patient to be transported on ECMO. Most ECMO centre staff will not be familiar with the retrieval environment. The principles of retrieval therefore need to be understood by the ECMO teams with the ideal solution being to combine the ECMO team with a standard retrieval team.

Box 4.3 Essential features of transport vehicles

- Readily available
- Adequate operational safety
- Capable of carrying (at least one) stretcher and mobile intensive care equipment set
- Safe seating for full medical team, including at head and side of patient
- Adequate space and patient access for observation and procedures
- Equipped with adequate supply of oxygen/other gases for duration of transports
- Fitted with medical power supply of appropriate voltage and current capacity
- Appropriate speed (coupled with) comfortable ride, without undue exposure to accelerations in any axis
- Acceptable noise and vibration levels
- Adequate cabin lighting, ventilation and climate control
- Fitted with overhead IV hooks, and sharps/biohazard waste receptacles
- Straightforward embarkation and disembarkation of patient and team
- Fitted with appropriate radios and mobile telephone

MODE OF TRANSPORT

There are three common types of transport vehicle used: road vehicles, aeroplanes (fixed wing) and helicopters (rotary wing). The basic requirements are listed in **Box 4.3** and their features and limitations are summarised in **Table 4.1**.

Ideally, dedicated vehicles should be used. Often the workload is insufficient to justify this and non dedicated

Table 4.1 Properties of transport vehicles

	ROAD	HELICOPTER	FIXED WING
Launch time	3–5 min	5–10 min (more if IFR)	30–60 min
Speed	10–120 km/h dependent on roads and traffic	120–150 knots (220–290 km/h), straight line	140–180 knots (piston) 230–270 knots (turboprop) 375–460 knots (jet)
Secondary transport	Not applicable	Sometimes	Inevitable
Effective range	0–100 km (longer if required)	50–300 km (longer or shorter in special cases)	200–2000 km
Noise	Low, except at high speed	Moderate to high (headsets required)	Low to moderate (cruise); higher on takeoff/landing
Vibrations	Variable with speed and road surface	Moderate in most phases (varies with rotor type)	Low in cruise; moderate or high on takeoff/landing
Accelerations	Variable and sometimes unpredictable in all axes	Minimal, and usually vertical only	Significant (fore/aft) on takeoff and landing
Special features	Base vehicles readily available	Versatility; point to point capability	Cabin pressurisation and all-weather capability (most)
Acquisition cost	Lowest	High (US$1–4.5 million new, depending on capabilities)	Moderate (piston) to very high (jet)
Operating costs (per km)	Intermediate	Intermediate to high	Low to intermediate

vehicles needing to be reconfigured are used. The mode of transport is based on a number of criteria:

- the availability of the transport vehicle
- the weather, especially if flying
- the distance to be travelled
- location and capability of the retrieval team
- the urgency of the case
- the clinical capability of the referring hospital.

The coordination and tasking centre takes all these into consideration. All things being equal, road is used for distances up to 40–80 km, rotary wing for 60–200 km and fixed wing for over 200 km.

ROAD AMBULANCE

This remains the most common form of transport and for some patients the safest even for long distances.

FIXED WING

Both propeller-driven and jet aircraft are used. Compared with helicopters, their faster speed needs to be offset with the need for a road leg at each end of the transfer. In comparison to helicopters lower noise and cabin pressurisation, often to sea level, and ability to fly in 'icing' conditions increase there utility. Most aeromedical fixed-wing aircraft are specifically configured with stretcher loading devices to assist in loading. Jets tend to be reserved for longer distance, greater than 800–1000 km.

HELICOPTERS

These remain the most high-profile and expensive vehicles used for patient transport. Most will require significant adaption to provide a reasonable working space. The lack of space makes procedures such as intubation almost impossible. They are very noisy to work in, with conversation only possible via intercom systems. This makes communication with patients difficult. It is only recently that the benefits of using a helicopter have been mainly for longer distances. Whereas a mix of single-engine and twin-engine aircraft have been used in the past, changes by regulatory authorities in Europe and Australia mean that most helicopter transports are now being performed in more suitable, larger twin-engine aircraft. The optimal range for use is a 'donut' of 40–300 km and their main advantage is the ability to land on hospital helipads, removing an additional road leg. This, of course, requires the hospital to have a helipad. Helicopter also have a role in the delivery of retrieval teams to trauma cases in high traffic density areas such as London.

SAFETY

Any mode of transport involves some risk to patients and staff. In the aeromedical environment unfamiliar personnel perform clinical tasks poorly,[17] so teams must be appropriately trained and equipped to function effectively and safely in each mode of transport. A senior member of the professional group concerned

should train and mentor new personnel on their first few trips.

A safety brief encompassing the use of safety equipment carried on the aircraft, emergency egress and actions to take during an emergency is essential. Daily meetings with helicopter flight crews is essential to improve effective communication between members of the team. This leads to an enhancing the safety of missions understanding between individual team members.

Dangerous activities such as unsafe driving and flying below safe minima are unacceptable. For aviation missions the decision whether a mission proceeds rests entirely with the aircraft pilot, and the attempt to coerce pilots to take risks has been recognised as a contributor to air ambulance accidents.[18] The pilot should be provided with only the details of where the team needs to go. Clinical details should generally not be given as this may influence the decision to proceed with the mission.

ALTITUDE AND TRANSPORT PHYSIOLOGY

Teams need to be aware of altitude-related changes in gas, volume, temperature and partial pressures of oxygen (**Table 4.2**).

Patients already dependent on oxygen will be further compromised by even modest increases in height requiring further oxygen supplementation. It is the partial pressure not the percentage of oxygen

Table 4.2 Changes with altitude

ALTITUDE (FEET/M)	PRESSURE (MMHG/KPA)	ALVEOLAR P_{O_2} (ON AIR)	(100% O_2)	GAS SPACE EXPANSION (%)	STD TEMP (°CELSIUS)	NOTES
Sea level	760 (≈100)	103	663	–	15	15°C is 'reference' average temp – actual obviously varies
1000 (300)	733 (≈97)	98	636	+3.6	13	Minimum altitude above ground level for helicopter transports
2000 (600)	706 (≈94)	94	609	+8	11	Likely altitude for most (VFR) helicopter flights over sea-level terrain
3000 (900) 4000 (1200)	681 (≈91) 656 (≈87)	89 85	584 559	+12 +16	9 7	Likely range of cabin altitude for standard flights in most turboprop air ambulance craft (e.g. Raytheon–Beech King Air series)
7000 (2000)	586 (≈78)	73	489	+29	1	Standard cabin altitude for airliners and most jet air ambulances (e.g. Lear 35)
10 000 (3000)	523 (≈70)	61	426	+45	–5	Likely ceiling of helicopter ops and hypoxic threshold in normal individuals
15 000 (4500)	429 (≈57)	45	332	+77	–14.5	Threshold for hypoxic decompensation in non-acclimatised individuals
20 000 (6000) 25 000 (7500)	349 (≈50) 282 (≈37.5)	34 30	252 185	+117 +170	–24.5 –34	Likely upper range of cruise altitude for turboprop aircraft Decompression at these altitudes causes rapid loss of consciousness and death without O_2
40 000 (12 000)	141 (≈19)	<10	61	+439	–56	Cruise ceiling for airliners and jets Limit for survivable decompression, even with 100% O_2 for flight crew

that is critical. Monitoring of Sa_{O_2} during ascent is essential.

GAS EXPANSION

Expansion of trapped gas in accordance with Boyle's law occurs in physiological and pathological air spaces and air-containing equipment such as endotracheal or tracheostomy tube cuffs, Sengstaken–Blakemore tubes and pulmonary artery balloons. Endotracheal tube cuff pressures will need to be adjusted during flight. Delivered tidal volumes may increase spontaneously in some ventilators, necessitating setting adjustments.

Physiological air spaces include the middle ear, nasal sinuses and GI tract. They can affect both patients and staff; consequently staff with upper respiratory tract infections or gastrointestinal disturbances should not fly.

Pathological air spaces include pneumothoraces, emphysematous lung bullae or cysts, intraocular and intracranial open injuries, bowel obstructions and gas emboli. These patients need to be transported at the lowest altitude possible. Most modern fixed-wing aircraft are capable of cabin pressurization, which decreases hypoxia and gas expansion. The pressurisation effectively replicates flying at a lower altitude – the so-called 'cabin altitude'. The difference between actual altitude and cabin altitude varies, with most air ambulances providing about 350 mmHg (≈50 kPa) differential. This equates to a cabin pressure of 3000 ft (≈900 m) while flying at 20 000 feet (≈6000 m). Most commercial airliners fly with a cabin altitude of around 7–9000 ft (≈2000–2700 m). Once the maximum differential is reached a lower cabin pressure can only be achieved by flying lower, which is often associated with more turbulence and increased fuel consumption. The medical team should only request a lower cabin height if clinically indicated.

Temperature falls 2°C for every 1000 ft (≈300 m) increase in height, as does the partial pressure of water, which is not corrected by cabin pressurisation. This can lead to dehydration especially on long trips.

PREPARATION FOR TRANSPORT

The preparation phase for transport will depend on the patient's clinical condition. The ideal is to spend sufficient time, including any urgent surgery, stabilising the patient so that the transport phase is uneventful. As with intra-hospital transport, this ideal may not be achievable, especially when the patient requires a time-critical intervention available only at the receiving destination. These missions are higher risk but are likely to be less futile than trying to stabilise an inevitably deteriorating patient. Prior to transport all patients must have a secure airway, either self-maintained or intubated and ventilated, and well-secured intravenous access. External bleeding should be controlled and investigations that may impact on the transport performed, if they can be performed in a short time frame. Heimlich-type valves may be attached to any chest drains rather than bulky UWSD (underwater seal drain) devices. The patient is transferred to the stretcher and secured with the patient harness. Any equipment is also attached securely to the stretcher bridge. Any documentation and copies of investigations need also to be taken. A checklist for departure and transport is recommended and provided in **Box 4.4**.

Box 4.4 Suggested pre-departure checklists

A. Before leaving hospital:	
• Patient identity and next of kin	Recorded
• Consent for transport	Obtained and documented
• Paperwork and X-rays	Collected
• Drugs for transport	Present and sufficient
• Emergency drugs/ equipment	Available
• Medical equipment	Collected and repacked
• Monitors, ventilator and infusions	Connected and on
• Tubes, lines, drains and catheters	Secured
• Altitude request (if applicable)	Passed to pilot
• Receiving unit	Contacted and updated
B. In vehicle and pre-departure	
• Stretcher and patient restraints	Secured and checked
• Oxygen supply	On and sufficient
• Monitors, ventilator and infusions	Working and secure
• Emergency drugs/ equipment	Stowed and accessible
• Other medical packs	Stowed
• Intravenous fluids	Hung and running
• Intravenous injection port	Accessible
• Medical power	On and connected
• Communications	Checked as applicable
• Seatbelts	On and checked
• Staff/patient headsets	On/checked (if applicable)

During the early stages of movement, special vigilance must be employed as this is the stage when equipment disconnections or physiological decompensation is likely to occur. During transport the patient is vulnerable to hypothermia and heating in the vehicle should be used.

HANDOVER

Handover to the receiving hospital is critical. Unless the patient needs immediate resuscitation there should be an opportunity for the retrieval team to have the exclusive attention of the receiving hospital. Various handover tools such as MIST (Mechanism of injury, Injuries suspected or found, Signs (vital signs) and Treatment given) are useful for trauma cases. ISOBAR has a wider

application to all patient groups and is being promoted as the standard handover tool in many areas:

- I – introduction
- S – situation
- O – observations
- B – background
- A – assessment
- R – recommendations.

Retrieval teams should use which handover tool is used in local practice. If one is not commonly used then ISOBAR will cover all the essential elements.

PRE-HOSPITAL CARE

Pre-hospital care of the acutely injured and critically ill is a complex and challenging field of medical practice. Ideally, patients should receive the most advanced required level of care at the earliest possible time, integrated with expedient transfer to the most appropriate definitive care facility. The ability to achieve this is both resource and system dependent with unique modifiers including transport platform logistics, environmental concerns and the need to integrate with other responding emergency services.

The benefits of adding a skilled critical care physician to the pre-hospital team are well recognised. Service models across Australasia and Europe reflect this belief.[19] The potential care delivered by such a team approaches or matches that only usually available in a tertiary hospital environment and may represent a 'definitive' requirement for the patient. However, the benefit of a physician and the safety and effectiveness of the team are maximised only if staff involved in such activities have the requisite skills and knowledge and are familiar with the pre-hospital and retrieval environment.

APPROACH TO THE SCENE AND SCENE SAFETY

During the approach to a trauma scene an opportunity exists to:

- identify potential hazards
- briefly 'read' the likely mechanism
- identify patient numbers, distribution and acuity of injury
- commence formulating a pre-hospital plan.

Scene assessment is critical to ensuring team, scene and, ultimately, patient safety.

It begins as soon as details of the task become available. The tasking agency may have access to further information that may be forwarded to the team en route.

In any pre-hospital emergency situation, scene safety is the primary concern and, as detailed above, plans for approaching the scene should be made on or prior to arriving.

The pre-hospital retrieval (PHR) team should adopt the 'safe self, safe team, safe scene, safe patient' approach.

PRE-HOSPITAL PLAN

A pre-hospital plan is a continuously evolving mental plan of action that the team will make as soon as it is activated, using the information given by the tasking agency. In many cases, this initial information is vague or incomplete, which reflects the problems experienced when receiving early phone calls about an incident. Although making a plan prior to arrival with limited information has drawbacks, there are clear benefits in arriving at the incident with a strategy for scene and patient management already in place. The plan often develops as the team travels to the scene and therefore valuable time en route should not be wasted.

When at the scene, the PHR team must have the skill to listen to all members of the emergency services and weigh up their suggestions as part of the overall plan. The ambulance service is the primary provider of pre-hospital care and paramedics are likely to be very experienced. It is worthwhile remembering that the physician-based pre-hospital teams are an extension of the ambulance service and not a replacement for them.

A generic pre-hospital plan could be:

- *the scene:*
  - a safe approach (self, team, scene and others)
- *the patient:*
  - likely requirements, need for extrication, assessment and stabilisation
- *the destination:*
  - triage options
  - transport platform options.

By having a pre-hospital plan, the team can add structure to their actions and, in doing so, develop a shared mental model inherent in teams that function in such high-acuity, high-consequence environments.

ENTRAPMENT AND EXTRICATION

Relative entrapment is a situation in which patients are trapped because of their injuries (e.g. a broken leg with disabling pain), location (e.g. a cave) or the ambient environment (e.g. a blizzard). If it were not for these factors, they would not require help in extricating themselves.

Actual entrapment occurs when patients are physically held in a location by the structure itself – for example, a major vehicle deformation with cabin intrusion, or a building collapse.

The aim is to remove the patient from an entrapped situation as safely and as quickly as possible. The key determinant in this plan (apart from safety) is the condition of the patient. The PHR team must decide on how to compromise between the slower, methodical extrication with total spinal control and the quicker

extrication of the less stable patient. Clearly, unstable patients will need rapid extrication but the ability to predict which patients are unsuitable for prolonged extrication due to the anticipated clinical course is more challenging. It may be better to compromise a degree of spinal protection earlier rather than have an emergency ('crash') extrication situation develop 30 minutes later.

The fire and rescue services will have access to the specialised equipment required. Without good teamwork between the services, the extrication will be significantly hindered.

ULTRASOUND IN THE FIELD

The availability of robust portable ultrasound machines has resulted in increased use in the pre-hospital or retrieval environment with good success; however, their use must be limited to people accredited in its use and must not result in undue delays in the patient management.

Physiotherapy in intensive care

Fiona H Moffatt and Mandy O Jones

Historically, physiotherapy in the ICU was confined to the treatment of respiratory problems performed routinely on all patients. Evidence-based practice has demonstrated that there is no longer a place for routine physiotherapy treatment in the ICU.[1] Physiotherapeutic intervention is based on clinical reasoning following the identification of physiotherapy-amenable problems, which are elucidated from a thorough systematic assessment.

There is still some debate about the precise role of the physiotherapist within the ICU, which may vary,[2] but the main features include:

- optimisation of cardiopulmonary function
- assistance in the weaning process utilising ventilatory support and oxygen therapy
- instigation of an early rehabilitation/mobilisation program to assist in preventing the consequences of enforced immobility
- advise on positioning to protect joints and to minimise potential muscle, soft tissue shortening and nerve damage
- optimisation of body position to effect muscle tone in the brain-injured patient
- optimisation of voluntary movement to promote functional independence and improve exercise tolerance
- management of presenting musculoskeletal pathology
- advise and education of family and carers
- liaison with medical and nursing staff on the continuation and monitoring of ongoing physiotherapy-devised care plans.

CARDIOPULMONARY PHYSIOTHERAPY

TREATMENT MODALITIES TO OPTIMISE CARDIOPULMONARY FUNCTION

Patients who are critically ill may present with impaired cardiopulmonary physiology secondary to both the underlying pathology and the therapeutic interventions employed to treat them. In their approach to any individual patient, the physiotherapist may use specific treatment techniques targeted at improving ventilation/perfusion (V/Q) disturbances, increasing lung volumes, reducing the work of breathing and removing pulmonary secretions. Physiotherapy treatment modalities may differ depending on the presence of an endotracheal tube, although patient participation with treatment is encouraged and promoted at the earliest point during intubation. Each intervention is rarely used in isolation, but rather as part of an effective treatment plan. Some physiotherapeutic techniques may have short-lived beneficial effects on pulmonary function, and some have no clear evidence to validate their effectiveness (**Table 5.1**).

LUNG HYPERINFLATION

Therapeutic lung hyperinflation has been used for many years by physiotherapists in the management of patients in the ICU.[3–7] Lung hyperinflation can be achieved through two techniques: manual hyperinflation (MHI) or ventilator hyperinflation (VHI).

Manual hyperinflation uses a self-inflating circuit to deliver a volume of gas 50% greater than tidal volume (V_T), to airway pressures up to 40 cmH_2O, via an endotracheal or tracheostomy tube. An augmented V_T may improve pulmonary compliance and aid recruitment of atelectatic lung, secondary to reduced air-flow resistance and enhanced interdependence via the collateral channels of ventilation.[8] Bronchial secretions may be mobilised by the increased expiratory flow rate and/or stimulation of a cough following a quick release of pressure from the bag on expiration.[9] The net effect can result in improved oxygenation.[8] However, MHI may be contraindicated in some ICU patients; therefore the use of ventilator hyperinflation offers an alternative method to augment lung volume whilst potentially avoiding cardiopulmonary instability associated with ventilator disconnection and loss of positive end-expiratory pressure (PEEP). The delivery of an augmented V_T via the ventilator (200 mL increments until a peak airway pressure of 40 cmH_2O is reached) has been shown to be as effective as conventional MHI in the removal of secretions and maintenance of static lung compliance.[10,11] In an emergency situation an Ambu-bag and facemask can be used to perform MHI in the self-ventilating patient. However, an alternative technique such as IPPB should be considered when an augmented V_T is required during a therapeutic intervention (**Box 5.1**).

Table 5.1 Treatment modalities to optimise cardiopulmonary function

INVASIVELY VENTILATED PATIENTS	NON-INVASIVE/SELF-VENTILATING PATIENTS
Manual hyperinflation (MHI) ventilator hyperinflation (VHI)	Active cycle of breathing technique (ACBT)
Suction	Manual techniques
Inspiratory muscle training	Positioning
Manual techniques	Intermittent positive-pressure breathing (IPPB)
Positioning	Continuous positive airways pressure (CPAP)
Mobilisation/ rehabilitation	Non-invasive ventilation (NIV) Nasopharyngeal/oral suction PEP mask, flutter valve, acapella Mobilisation/rehabilitation

Box 5.1 Potential advantages and complications of MHI

Potential advantages

Reversal of acute lobar atelectasis[8]
Alveolar recruitment via channels of collateral ventilation[8]
Improvement in arterial oxygenation
Mobilisation of secretions and contents of aspiration[11]
Improved static lung compliance[11]
Effectiveness may be increased when combined with appropriate positioning and manual techniques[1]

Potential complications

Absolute contraindications include undrained pneumothorax and unexplained haemoptysis
Cardiovascular and haemodynamic instability[6]
Loss of PEEP, inducing hypoxia and potential lung damage. This can be minimised by incorporating a PEEP valve into the circuit of a 'PEEP-dependent' patient
Risk of volutrauma, barotrauma and pneumothorax, which can be reduced by including a manometer in the circuit
Risk of increased intracranial pressure
Increased patient stress and anxiety

RECRUITMENT MANOEUVRES

Recruitment manoeuvres may be employed to reverse hypoxaemia in patients with ALI/ARDS. A recruitment manoeuvre involves a transient increase in transpulmonary pressure in an attempt to re-inflate and maintain atelectatic lung units.[12] No standard approach exists; however, common options include: the application of incremental levels of continuous positive airways pressure (CPAP) with no tidal excursion, incremental increases in positive end-expiratory pressure (PEEP) with additional V_T, and the application of intermittent larger 'sigh' breaths. In randomised studies, although recruitment manoeuvres may transiently improve oxygenation, there is as yet no proven outcome benefit.[13]

Box 5.2 Potential advantages and complications of suction

Potential advantages

Stimulation of a cough when reflex is impaired by mechanical stimulation of the larynx, trachea or large bronchi
Removal of secretions from central airways when cough is ineffective or absent

Potential complications

Tracheal suction is an invasive procedure and should be undertaken only when there is a clear indication
Absolute contraindications to suctioning are unexplained haemoptysis, severe coagulopathies, severe bronchospasm, laryngeal stridor, base of skull fracture and a compromised cardiovascular system
Hypoxaemia can be induced secondary to suctioning. This can be limited by pre- and post-oxygenation
Cardiac arrhythmias may be more common in the presence of hypoxia
Tracheal stimulation may produce increased sympathetic nervous system activity or a vasovagal reflex producing cardiac arrhythmias and hypotension

SUCTION

Suction is used to clear secretions from central airways when a cough reflex is impaired or absent. A suction catheter is passed via an endotracheal or tracheostomy tube or via a nasal/oral airway to the carina, which may stimulate a cough in a non-paralysed patient (**Box 5.2**). The catheter is pulled back 1 cm before suction is applied on withdrawal. The suction catheter diameter should not be greater than 50% of the diameter of the airway through which it is inserted as large negative pressure can be generated intrathoracically without air entrainment. The use of suction following effective MHI optimises removal of secretions.[14] Instillation of normal saline prior to suctioning remains controversial; however, it may stimulate a cough, maximising secretion mobilisation and clearance.

INSPIRATORY MUSCLE TRAINING

It is recognised that mechanical ventilation and prolonged immobility may result in widespread deconditioning; this can include weakness or fatigue of the diaphragm and inspiratory muscles, plus poor respiratory muscle endurance,[15] resulting in slow or failed weaning from ventilatory support.[16] It has been suggested that mechanical ventilation per se may adversely alter diaphragmatic myofibril length and function, leading to rapid atrophy.[15] A recent systematic review evaluating the effect of inspiratory muscle training on muscle strength in adults weaning from mechanical ventilation reported a significant increase in inspiratory muscle strength following muscle training.[17] However,

it remains unclear whether this increased strength is associated with a shorter duration of mechanical ventilation, improved weaning or patient survival.

MANUAL TECHNIQUES

CHEST SHAKING AND VIBRATIONS

Shaking and vibrations are oscillatory movements of large and small amplitude performed during expiration, which are thought to increase expiratory flow rate, aiding mucociliary clearance.[18] The application of chest wall shaking and vibrations is not standardised, but their effectiveness is thought to be influenced by the timing of their application within the breath cycle. Shaking and vibrations applied early in the expiratory cycle have been shown to generate high peak inspiratory pressures, whereas shaking and vibrations applied late in the expiratory cycle are not effective at increasing peak expiratory flow.[19]

CHEST WALL COMPRESSION

Compression of the chest wall can be used to augment an expiratory manoeuvre such as a ‘huff’ (see section on ACBT) or a cough by providing tactile stimulation or wound support.

CHEST CLAPPING/PERCUSSION

Chest clapping is a rhythmical percussion applied over specific areas of the chest, which may mobilise secretions secondary to the transmission of mechanical oscillations through the chest wall. However, there is little evidence to support this claim.

NEUROPHYSIOLOGICAL FACILITATION (NPF) OF RESPIRATION

NPF of respiration is a set of techniques designed for the treatment of the neurologically impaired adult. Manual externally applied stimuli to the thorax, abdomen and mouth can be used to stimulate increased V_T, a cough reflex, augmented contraction of the abdominal muscles, or an increased conscious level.[20,21]

POSITIONING

A simple change of position can have a profound effect on cardiopulmonary physiology (**Fig. 5.1**).[22,23] As such, positioning is commonly utilised to achieve several different goals: drainage of secretions using gravity-assisted positioning (GAP), reduction of the work of breathing/breathlessness or to optimise ventilation/perfusion (V/Q) matching.

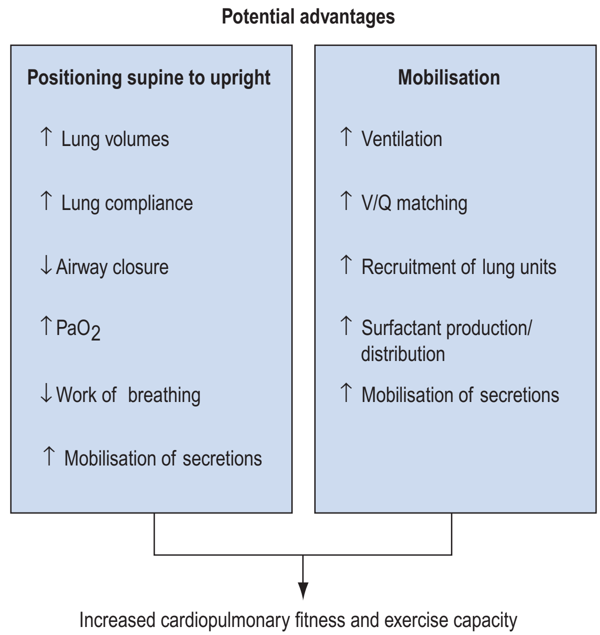

Figure 5.1 Potential advantages and complications of mobilisation. *(Adapted from Dean 1998,[22] with permission.)*

GRAVITY-ASSISTED POSITIONING (GAP)

GAP facilitates the removal of excess bronchial secretions by positioning a specific bronchopulmonary segment perpendicular to gravity (**Box 5.3**). This technique is not used in isolation but in conjunction with augmented VT, either via the ventilator, MHI or the active cycle of breathing techniques (ACBT) in a spontaneously breathing patient. An individual position exists for each bronchopulmonary segment based on the anatomy of the bronchial tree;[24] however, these may need modification in the ICU setting.

Box 5.3 Potential advantages and complications of GAP

Potential advantages
- Maximises removal of excess bronchial secretions when combined with ACBT
- Allows accurate treatment of specific bronchopulmonary segments
- Self treatment can be included in a home programme on discharge

Potential complications
- Positions need modification when used in the presence of cardiovascular/neurological instability, haemoptysis or gastric reflux

REDUCTION OF THE WORK OF BREATHING

A reduction in the work of breathing/breathlessness can be achieved by putting a patient in a position that optimises the length–tension relationship of the diaphragm, promotes relaxation of the shoulder girdle and upper chest and facilitates the use of breathing control.[25] This approach to positioning is particularly effective when used in conjunction with non-invasive ventilation (NIV). Adequately supported high-side lying is a useful position to promote relaxation of the breathless

patient. In addition, it can discourage the overuse of accessory muscles of respiration, which may reduce energy expenditure. Some patients prefer forward lean sitting with their arms placed in front of them on a high table. In this position the length–tension relationship of the diaphragm is optimised secondary to forward displacement of the abdominal contents.

VENTILATION/PERFUSION

Appropriate positioning of a patient can maximise V/Q.[26] In the self-ventilating adult, V/Q matching increases from non-dependent to dependent areas of lung.[27] However, in adults receiving positive-pressure ventilation lung mechanics are altered producing V/Q inequality. In this situation non-dependent areas of lung are preferentially ventilated while dependent regions are optimally perfused; as such a regular change of position is recommended.

In an extreme form prone positioning has been used to improve refractory hypoxaemia in patients with acute lung injury (ALI)/acute respiratory distress syndrome (ARDS). The mechanisms behind these improvements are complex, but probably centre around a combination of a redistribution of some pulmonary perfusion together with a more homogeneous distribution of ventilation leading to improved V/Q matching. Although prone positioning improves oxygenation in up to 70% of those with ALI/ARDS, its role in improving outcome remains controversial.[28]

ACTIVE CYCLE OF BREATHING TECHNIQUE

The ACBT is a cycle of breathing exercises used to remove excess bronchial secretions (**Box 5.4**).[5] The cycle can be adapted for each patient according to existing underlying pathology and presenting clinical signs. It consists of:

- breathing control × 4–6 breaths
- normal tidal breathing using the lower chest
- minimising the use of accessory muscles of respiration
- promoting relaxation
- lower thoracic expansion × 4–6 breaths
- can be used with/without an inspiratory hold
- forced expiration technique
- expiration with an open glottis ('huff'), combined with breathing control.

Although mainly used in the self-ventilating patient, alert, cooperative, ventilated patients can participate with this technique. The ACBT can be delivered via MHI in sedated and ventilated patients requiring mobilisation of secretions and airway clearance.

Box 5.4 Potential advantages and complications of ACBT

Potential advantages
- Mobilises and clears excess bronchial secretions[28]
- Improves lung function[28]
- Minimises the work of breathing
- Individual components of the cycle can be utilised/emphasised to target specific problems
- Can be used in combination with other manual techniques, GAP, V/Q matching, positioning to reduce breathlessness, and during activities such as walking
- Self treatment can be included in a home programme

Potential complications
- Without adequate periods of breathing control, bronchospasm and desaturation can occur
- Poor technique can lead to ineffective treatment and unnecessary energy expenditure

MECHANICAL ADJUNCTS

INTERMITTENT POSITIVE-PRESSURE BREATHING

IPPB is a patient-triggered, pressure-cycled mechanical device mainly used in self-ventilating patients to increase ventilation, mobilise bronchial secretions and re-expand lung tissue by augmenting V_T (**Table 5.2**).[29] Positive airway pressure is maintained throughout inspiration. Expiration is passive. IPPB requires constant adjustment of pressure and flow rates and careful patient monitoring to maintain effectiveness and cooperation. Effectiveness is increased when used in conjunction with positioning, ACBT and manual techniques (**Box 5.5**).

Table 5.2 Site and action of IPPB, CPAP and NIV

	IPPB	CPAP	NIV
Lung volume affected	↑ V_T	↑ FRC	↑ V_T and FRC
Action	Assists removal of excess bronchial secretions	Reverses atelectasis	Ventilatory support

CONTINUOUS POSITIVE AIRWAYS PRESSURE

CPAP maintains a positive airway pressure throughout inspiration and expiration. It is used in both intubated and self-ventilating patients to increase/normalise functional residual capacity (FRC) via recruitment of atelectatic lung. Clinically increased FRC is associated with improved lung compliance, improved oxygenation and reduced work of breathing.[29] Effectiveness is increased when used in conjunction with appropriate positioning. The self-ventilating patient must be able to generate an adequate V_T as this volume is not augmented with CPAP (see Table 5.2).

NON-INVASIVE VENTILATION

In recent years there has been an expansion in the role of NIV in the ICU. This includes the prevention of invasive ventilation in patients with COPD,[30] pulmonary oedema and immunocompromise; early weaning from mechanical ventilation and potentially the prevention

Box 5.5 Potential advantages and complications of IPPB, CPAP and NIV

Potential advantages
Improves lung volumes
Improves gaseous exchange
Decreases the work of breathing
IPPB and NIV can mobilise excess bronchial secretions by improving V_T
IPPB and NIV can improve lung and chest wall compliance
CPAP reduces left ventricular afterload by reducing the transmural pressure gradient
Patients can be mobilised while on CPAP and some modes of NIV; alteration of ventilator settings might be indicated to maximise patient potential/exercise tolerance during treatment
Settings can be adjusted to augment physiotherapy intervention, e.g. increased IPAP to assist removal of secretions
Potential complications
Absolute contraindications include severe bronchospasm, undrained pneumothorax, pneumomediastinum, unexplained haemoptysis and facial fractures; use with care in pre-existing bullous lung disease
Haemodynamic/neurological instability
Risk of decreased urine output with CPAP and NIV
Risk of carbon dioxide retention with CPAP
Risk of aspiration

of re-intubation in those who suffer extubation failure. In addition, V_T may be augmented during physiotherapy treatment to remove secretions, or when mobilising the patient (see Table 5.2). Improved oxygenation may be achieved using NIV when the patient is positioning to optimise V/Q (see Box 5.5).

TREATMENT ADJUNCTS AND TECHNIQUES

PEP mask and oscillating PEP devices such as the Flutter and acapella® are specialised mucociliary clearance devices used by some patients with chronic lung disease. These devices are rarely introduced in the ICU setting.

CRITICAL CARE REHABILITATION

The effects of deconditioning on the cardiovascular (**Box 5.6**), respiratory (**Box 5.7**) and neuromusculoskeletal (**Box 5.8**) systems are well documented.[31–33] This phenomenon occurs as a result of restricted physical activity, and reduces the ability to perform work. Such physical dysfunction can occur with even relatively short periods of immobility, and is significantly influenced by age, pre-morbid condition, nature of the illness/injury, and biochemical/pharmacological factors.[34,35] The consequences of physical dysfunction are significant in terms of patient outcome, length of hospital stay, duration of rehabilitation and subsequent ability to function independently in the community.[34–38] Consequently, there has been a paradigm shift in critical care management to reduce confounding iatrogenic factors and minimise immobility. Care bundles such as the ABCDE (Awakening and Breathing coordination, Choice of sedative or analgesic exposure, Delirium monitoring and management, Early mobility and Exercise) approach have been advocated in order to optimise patient recovery and outcome.[38,39]

The role of early mobility and exercise in attenuating the deleterious effects of immobility during critical illness is now widely reported.[40] Early mobilisation and/or exercise of critically ill patients via selected rehabilitation strategies has been demonstrated to be

Box 5.6 Deconditioning and the cardiovascular system[31,33]

↓ stroke volume – ventricular remodeling and reduced preload (see ↓ plasma volume)
↑ heart rate (resting and exercising) – ↓ vagal tone, ↑ sympathetic catecholamine secretion and ↑ cardiac β-receptor activity
↓ cardiac output and systemic oxygen delivery
↓ V_{O_2}max – magnitude highly correlated to duration, static exercise effective in preventing some of decrease. Related to changes centrally (cardiac output) and peripherally (oxygen delivery and utilisation)
↓ plasma volume – secondary to fluid shift and altered renin–antiotensin–aldosterone activity. Contributes to ↓ orthostatic tolerance
Orthostatic intolerance develops more rapidly in the elderly or those with cardiovascular pathology; often slow to resolve
Increased blood viscosity and vascular stasis – predisposition to thromboembolism
Altered cardiovascular reflexes – proposed attenuated baroreflex-mediated sympathoexcitation and enhanced cardiopulmonary receptor-mediated sympathoinhibition; contributes to orthostatic intolerance
Altered arterial/venous vascular function

Box 5.7 Deconditioning and the respiratory system

Adverse effects on:
- FRC
- Compliance (lung and chest wall)
- Resistance
- Closing volume
- Respiratory muscle function – impaired strength and endurance, reduced performance of ventilatory pump, ↑ days of mechanical ventilation, complex weaning issues
- Concept of ventilator-induced diaphragmatic dysfunction proposed (atrophy, fibre remodelling, oxidative stress, and structural injury); time-dependent reduction in force-generating capacity, secondary to disuse and passive shortening
- Respiratory muscle weakness may be limited by judicious choice of ventilation mode; role of inspiratory muscle training unclear

Box 5.8 Deconditioning and the neuromusculoskeletal system

Muscle atrophy – protein degradation (loss of contractile protein, increased non-contractile tissue, e.g. collagen) and cytokine activity. Reduction in strength, especially lower-limb antigravity muscles (i.e. those involved with transferring and ambulation). Inactivity amplifies the catabolic response of skeletal muscle to cortisol, therefore more marked atrophy following trauma or illness. Particularly significant in patient groups with low relative muscle mass, e.g. the elderly. Nutritional countermeasures should be considered and carefully titrated to best meet demands

↓ Muscle endurance (cf. Box 5.7 Respiratory system) – reduced muscle blood flow/red cell volume/capillarisation/oxidative enzymes, and biochemical changes. Generally longer to rehabilitate compared with reduction in muscle strength

Muscle shortening or changes in peri/intra-articular connective tissue (including chest wall and thoracic spine) → contractures, ↓ joint range of motion, pain. Positioning and stretching maintain range and delay invasion of non-contractile protein

Decreased bone mineral density (particularly trabecular bone) – may be attenuated by standing or resistance exercise. Rate of recovery tends to lag behind that of muscle strength. Increased risk of fracture on remobilisation, especially in elderly

Microvascular and biochemical changes in peripheral nerves impair neuromuscular function. Adversely affects maximal voluntary contraction, and balance/proprioceptive activity

Critical illness neuropathy and myopathy frequently develop in patients hospitalised in an ICU for >1 week. Risk factors include sepsis, SIRS and severe MOF. Associated with higher mortality rate, prolonged ventilation and rehabilitation, disability and reduced quality of life

safe, feasible, reduce length of stay, decrease the incidence of delirium and improve physical function.[40–43] Based on growing evidence, the European Respiratory Society, the European Society of Intensive Care Medicine, and the National Institute For Health and Clinical Excellence[44] have promoted early instigation of individualised rehabilitation programmes to prevent avoidable physical dysfunction.[44,45] Early mobilisation programmes may, however, face cultural and technological barriers[34,46] and proponents advocate a shift from multidisciplinary 'silos' to collaborative interdisciplinary care.[38,47] The physiotherapist, possessing expertise in rehabilitation and exercise physiology, should play a key coordination role in these programmes by evaluating individual patients, devising a shared therapeutic strategy, and referring to other rehabilitative specialties (e.g. speech and language therapy, occupational therapy) as required.[45]

Careful assessment both before (and during) implementation of an early mobilisation/exercise programme must be undertaken by a suitably experienced

Box 5.9 Criteria to consider before mobilising a critically ill patient[40,41,46,48]

Past history
Premorbid physiological reserve
Premorbid functional ability
Current cardiovascular reserve
Resting HR <50% of age-predicted maximum
BP <20% variability recently
No new MI or arrhythmias
No orthostatic intolerance
No new antiarrhythmics or vasopressors (or escalating doses of vasopressors)
Other significant cardiovascular concerns excluded
Current respiratory reserve
$Pa_{O_2} : Fi_{O_2}$ >40 kPa
Sa_{O_2} >90% and <4% recent drop
Satisfactory respiratory pattern
PEEP <10, Fi_{O_2} <60%
Concern for airway integrity
Patient–ventilator synchrony
Other factors
Risk assessment undertaken (including environment, staffing, expertise, equipment)
Patient consent
No neurological contraindications
No orthopaedic contraindications
No undue pain, fatigue, anxiety or dyspnoea
Adequate nutritional status
Liaison with interdisciplinary team, patient and/or family
Consideration of objectives and outcome measures

physiotherapist. A number of authors have suggested algorithms or criteria for this process,[40,42,48,49] which are summarised in **Box 5.9**.

Traditionally, exercise rehabilitation has progressed linearly from activity in bed, then sitting, and finally to standing/walking. The model demonstrated in **Figure 5.2** represents a three-stage functional rehabilitation programme. It is supported by evidence that suggests a multimodal training regimen is required to maintain/restore both physiological and psychological performance after a period of immobility and illness.[50] The use of interlinking circles is intended to reflect the non-linear pattern of exercise progression more commonly utilised in patients with critical illness (e.g. patients may be able to stand using a tilt-table before they are able to tolerate sitting out of bed). The central shaded area represents the core components that should be addressed at every stage in the patient's recovery. The areas bordered by the broken lines represent the progression or regression from one stage to the next. During all stages, the patient's cardiopulmonary response must be closely monitored and exercise titrated accordingly. Modifications (e.g. temporarily increasing the Fi_{O_2} and/or level of ventilatory assistance) during exercise and in the early post-exercise period may be necessary. Such modifications are

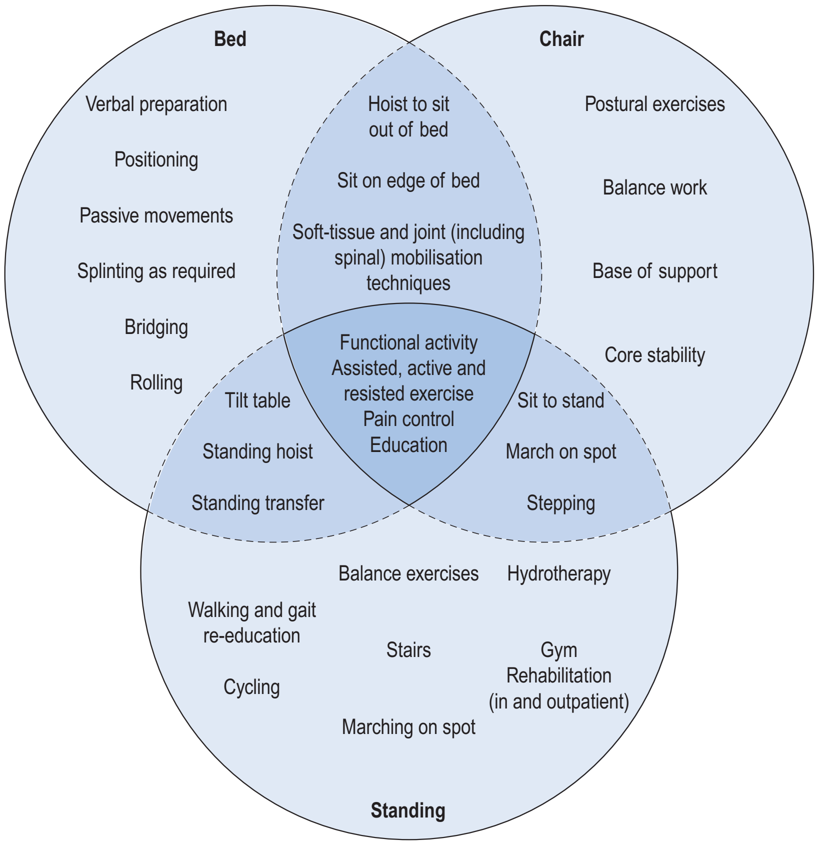

Figure 5.2 Schemata representing three-stage functional rehabilitation programme (the Nottingham Critical Care Rehabilitation Model). *(Douglas E. The Nottingham Critical Care Rehabilitation Model, University of Nottingham Division of Physiotherapy, Personal Communication, 2006, with permission.)*

commonly required as increasing physical activity often coincides with weaning from ventilatory support – both significant challenges to the physiological reserve. All aspects of progressive exercise therapy should be considered including positioning, passive and active mobilisation, aerobic training and muscle strengthening.[45] Adjuncts such as continuous passive motion, splinting or neuromuscular electrical stimulation may also be warranted.

The wealth of evidence regarding deconditioning should play a central role in planning treatment, both preventative and rehabilitative. For example, those muscle groups known to be most adversely affected by disuse should be the first to be targeted with a gradual, progressive regimen. During the remobilisation period, the interdisciplinary team must be particularly mindful of those elements with delayed recovery – for example, orthostatic tolerance and bone mass (predisposition to falls and fractures), and muscle endurance (diminished exercise tolerance).

It has been suggested that, in order to improve long-term outcomes for survivors of ICU (e.g. late mortality, ongoing morbidity, neurocognitive defects, functional disability, quality of life, economic burden), critical illness and its management should be viewed on a continuum and not merely the time spent in a critical care facility.[36] As such, rehabilitation should reflect this, continuing into the community, outpatient or follow-up clinic setting (Douglas, personal communication, 2006). Although the psychological, cardiopulmonary and functional sequelae of critical care survival may be profound (**Table 5.3**) to date, the optimal strategies for delivering post-critical care rehabilitation services remain unclear.[51,52]

PHYSIOTHERAPY ROLE EXPANSION

The nature of the critical care environment offers diverse opportunities for role expansion. The lead physiotherapist for the service must possess specialist cardiopulmonary and rehabilitative skills, as well as an expert knowledge of exercise physiology in health and disease. Furthermore, as a member of a dynamic interdisciplinary team, it may be appropriate to extend diagnostic or clinical skills beyond the remit of conventional physiotherapy (e.g. developing weaning strategies, advanced tracheostomy management, bronchoscopy, prescription, arterial blood gas sampling, managing non-invasive ventilation services, etc.).

As an educator, the clinician must ensure that all professionals who provide physiotherapy input are competent in their assessment, clinical reasoning and

Table 5.3 Psychological, cardiopulmonary and functional problems often encountered after ICU discharge

PSYCHOLOGICAL	CARDIOPULMONARY	FUNCTIONAL
Depression	Compromised cardiopulmonary system	Back pain
Fear	Difficulty clearing retained secretions (trache tube, mini-trach in situ)	Shoulder pain
Anxiety	Decreased lung volumes	Muscle atrophy/decreased strength
Confusion	Oxygen dependency	Inability to carry out activities of daily living independently
Disorientation		Limited mobility
Flashbacks		Poor exercise tolerance
Lack of motivation		Poor gait pattern
Functional dependence		

skill execution. A commitment to audit and research is essential in order to ensure evidence-based service provision, clinical governance and best possible patient outcome.

PHYSIOTHERAPY AND CRITICAL CARE OUTREACH TEAMS

The development of specialist physiotherapist posts within critical care outreach teams (CCOT) constitutes a prime example of role expansion. Following the publication of 'Comprehensive critical care',[53] CCOT services were developed to meet the actual or potential needs of patients through critical care provision 'without walls':

- avert critical care admission where possible
- facilitate timely critical care admission when appropriate
- empower all health care staff by disseminating ward-based critical care skills
- optimise patient management and make best use of critical care resources via effective clinical decision making.

The introduction of CCOT has been associated with a varied approach to team configuration; however, it has been suggested that those following a multiprofessional model are most likely to affect clinical and organisational improvements.[54] Consequently, many teams have elected to employ a designated specialist physiotherapist who can bring physiotherapeutic expertise to the service whilst also developing generic outreach practitioner skills (e.g. advanced tracheostomy management, cannulation, venipuncture, prescription via patient group directions, arterial blood gas sampling, drug administration, advanced life support, management of central/peripheral lines, 12-lead ECG interpretation, ordering/interpreting blood results, non-invasive ventilation, intravenous fluid management and chest X-rays).

SUMMARY

The physiotherapist has an important and varied role within the ICU/HDU setting working as part of the interdisciplinary team to optimise cardiopulmonary function and functional ability. The physiotherapist is often uniquely placed to follow and treat a patient from the acute stages at ICU admission, through the rehabilitation process to subsequent discharge from hospital and, if necessary, treatment can be continued in the outpatient setting.

There is no longer a place for routine physiotherapy treatment. Regular systematic assessment will identify physiotherapy-amenable problems that contribute to an interdisciplinary care plan. Implementation of any physiotherapy treatment should always utilise continuous analytical reassessment.

Critical care nursing

John R Welch

NATURE AND FUNCTION OF CRITICAL CARE NURSING

Nurses are the round-the-clock constant for critically ill patients and their families, providing continuity and acting as the 'glue' that holds the service together. Nurses fine-tune, coordinate and communicate the many aspects of treatment and care needed by the patient, with:

- continuous, close monitoring of the patient and attached apparatus
- dynamic analysis and synthesis of complex data
- anticipation of complications
- complex decision making, execution and evaluation of interventions so as to minimise adverse effects
- enhancement of the speed and quality of recovery
- emotional support of the patient and family, including support through the end-of-life.[1]

Nursing in critical care is influenced by the essential nature of nursing as well as the specific requirements of the speciality. Key concepts for all nurses are said to include an appreciation of holism and the whole range of influences on all areas of life, and the pursuit of health rather than treatment of illness.[2]

There is inevitably an emphasis on technology in the intensive care unit (ICU): nurses must be technically competent. It is all too easy to neglect the human aspects of care. Expert nurses connect with patients both physically and psychologically,[3] but patient-centred care and emotional support can be lost when the nursing resource is reduced.[4] One ICU patient described his treatment as 'rooted in the minute analysis of charts and the balancing of chemicals, not so much in the warmth of human contact'.[5] Others reported feelings of helplessness, desertion and powerlessness.[6] ICU patients are less heavily sedated and therefore more aware than previously, but can rarely control what happens to them during critical illness, especially in the acute phase. They usually wish to reassert their autonomy as they recover (e.g. during weaning from ventilation or when moving to a lower level of care). Nurses can enable patients to have a say in the management of these processes while still ensuring a safe progression. Essential personal care is invariably undertaken or supervised by nurses; and although important functions such as chest physiotherapy, mobilisation and administration of nutrition may be prescribed by other specialists, they will still be integrated and delivered by nurses.

A SYSTEMATIC APPROACH TO CARE

Nursing the critically ill patient is complex. The clinical review should be structured in order to clarify and prioritise patient needs so that all possible problems are addressed. In acute situations, assessment in turn of the fundamental A–B–C–D–E aspects of care is a useful method:

A. *airway:* with establishment and maintenance of airway patency (using artificial devices when necessary, removal of pulmonary secretions, etc.)
B. *breathing:* ensuring adequacy of oxygenation and ventilation, etc.
C. *circulation:* assessing blood volume and pressures; perfusion of brain, heart, lungs, kidneys, gut and other organs; control of bleeding, haematology, etc.
D. *disability:* checking level of consciousness/reduced consciousness, and the factors that affect it; systemic and localised neurology
E. *exposure:* hands-on, head to toe, front and back examination, and review of everything else; with consideration of wounds and drains; electrolytes and biochemistry, renal function, etc.

Treatment strategies can be prioritised using this schema, which has the additional benefit that it will be familiar to colleagues trained in advanced life support and similar systems.

Further detail may be gained from review of:

F. *fluid* and electrolyte balance, fluid input, urine output
G. *gastrointestinal function:* nutritional needs; elimination
H. *history* and holistic overview of the patient as a person and their socio-cultural context
I. *infection* and infection control; microbiology
L. *lines:* utility and risks
M. *medications*
N. *nursing* and interdisciplinary teamwork: ensuring resources are sufficient for the patient's severity of illness and the physical demands of care

P. *psychology*: and the plan of care and prognosis in the short, medium and longer term.[7]

More sophisticated models can be used to frame a wider impression of the patient or to reflect a particular philosophy or approach to care.[8] There is a great benefit in developing a shared vision within the department, and in articulating how agreed values will be demonstrated in practice.[9] These might include emphasising the primary importance of patient safety and well-being, ensuring that the kindness an individual would want for their own loved ones is always offered, effective teamworking, and having systems in place to achieve continuous improvement.[10] Whichever method is used, there must be explicit definitions of the patient's problems and a clear statement of measurable therapeutic goals.

NURSING AND PATIENT SAFETY

Many patients suffer iatrogenic harm, but bedside nurses have the opportunity to prevent such incidents by intercepting and mitigating errors made by others.[11] No particular system of critical care nursing has been shown to be definitively superior to others,[12] but nursing surveillance is key to patient safety.[13] Insufficient staffing has been linked to increased adverse events, morbidity and mortality.[14] At the minimum, 5.6 nurses need to be employed for each patient requiring 1:1 care 24 hours a day.

EVOLVING ROLES OF CRITICAL CARE NURSES

Critical care nurses' range of practice has widened with progress in technology and changes in the working of other professionals, although the benefits of developing new skills must be balanced against ensuring the maintenance of fundamental care. There is great variation in the array of tasks undertaken by nurses in critical care in different institutions, with invasive procedures and drug prescriptions still usually performed by doctors. Since 2006 qualified nurse prescribers in the UK have been enabled – in theory at least – to prescribe licensed medicines for the whole range of medical conditions. As yet, nurse prescribing is not a widespread phenomenon in critical care but is likely to become a routine part of practice in the future.

Critical care nurses have a rapidly developing role in decision making regarding the adjustment, titration and troubleshooting of such key therapies as ventilation, fluid and inotrope administration, and renal replacement therapy. The use of less-invasive techniques (e.g. transoesophageal Doppler ultrasonography for cardiac output estimation) mean it is possible for nurses to institute sophisticated monitoring and administer appropriate treatments. There is evidence that nurses can achieve good outcomes in these areas, especially with the use of clinical guidelines and protocols (e.g. by reducing the time to wean respiratory support[15]). It is clear that further development of protocols, guidelines and care pathways can be used to enhance the nursing contribution to critical care.

NEW NURSING ROLES IN CRITICAL CARE

Maintaining adequate numbers of staff with the experience and skills to meet the increasing needs of critically ill patients is a challenge. Nurses constitute the largest part of the workforce and represent a significant cost. Changes in training arrangements and the demographics of nurses in general have meant that there are relatively fewer applicants for ICU posts. This has necessitated the development of various new ways of working to deliver both fundamental and more sophisticated aspects of care. New nursing roles include some that substitute for medical roles, as well as those that retain a nursing focus and aim to fill gaps in health care with nursing practice rather than medical care. The UK has designated a number of senior 'nurse consultant' posts in all areas of health, but with the largest proportion in critical care, particularly in outreach roles.[16] These are advanced practitioners focusing primarily on clinical practice but also required to demonstrate professional leadership and consultancy, development of practical education and training, macro-level practice, and service development, research and evaluation.

Other staff – such as 'nursing' or 'health care assistants' – are increasingly and successfully employed to deliver what has previously been seen as core nursing care, in order to support trained nurses and free them to concentrate on more advanced practice.[17] Reductions in health care funding and shortages of trained staff are likely to make such developments more common, but it is imperative that this is a managed process so as to ensure the best outcomes for patients, with proper arrangements for training, support and systems of work.

CRITICAL CARE NURSING BEYOND THE ICU: CRITICAL CARE OUTREACH (SEE)

Around the world, general ward staff are required to manage an increasing throughput of patients who are, on average, older than before, with more chronic diseases, and more acute and critical illness. A national review of critically ill ward patients showed that the majority experienced substandard care before transfer to the ICU.[18] Various factors are implicated, including knowledge deficits and failure to appreciate clinical urgency or seek advice, compounded by poor organisation. It is nurses who record or supervise the recording of vital signs, but there is often poor understanding of the importance of such indicators, ineffective communication with senior staff, and difficulties ensuring that appropriate treatments are prescribed and

administered. Nurse-led critical care outreach teams support ward staff caring for at-risk and deteriorating patients, and facilitate transfer to ICU when appropriate.[19] They can also support the care of patients on wards after discharge from ICU,[20] and after discharge from the hospital too. Potential problems with these approaches include a loss of specialist critical care staff from the ICU, and being sure that outreach teams have the necessary skills to manage high-risk patients in less well-equipped areas, particularly when there are limitations placed on nurses prescribing and administering treatments.

NURSING IN THE INTERDISCIPLINARY TEAM

High-quality critical care requires genuine interdisciplinary teamwork, with:

- 'clear individual roles
- members who share knowledge, skills, best practice and learning
- systems that enable shared clinical governance, individual and team accountability, risk analysis and management'.[21]

ICUs where team performance is not so well developed are likely to have less effective processes and worse outcomes. Aspects of team leadership, coordination, communication and decision making can be measured against defined criteria, as can outcome indicators relating to patients and staff.[22] Indicators of team performance include:

- compliance with protocols
- adverse events/critical incidents
- patient length of stay
- mortality
- staff satisfaction
- staff retention.[22]

Identified deficiencies in teamworking can then be addressed, although some investment may be needed. A recent study focused on nurses as the main drivers of improvement in the ICU. Units engaged in a structured improvement programme entailing analysis of the prevailing culture in the department, followed by tailored training in teamworking, ways of achieving safer practice, and performance measurement.[23] ICUs that completed this programme had significantly better outcomes than those that did not, even though both groups were required to use the same clinical protocols.[23]

QUALITY OF CARE

Robust audit is the foundation of quality care. Potential indicators include pressure ulcer prevalence, nosocomial infection rates, errors in drug administration, and patient satisfaction.[24] Nurses must measure the quality and take responsibility for the care that they deliver, although it should be appreciated that nursing care cannot be considered entirely separately from other variables that influence patient outcomes. The interdependence of different critical care personnel was illustrated in a multicentre investigation where interaction and communication between team members were more significant predictors of patient mortality than the therapies used or the status of the institution.[25] Quality care depends on a collective interdisciplinary commitment to continuous improvement.[26]

CRITICAL CARE NURSING MANAGEMENT

The nurse manager role is crucial to service performance. The most important priority is the challenge of attracting and retaining a flexible, effective and progressive nursing team that works well with other health care professionals in order to meet patient needs, but within a limited budget.

STAFFING THE CRITICAL CARE UNIT

The starting point for calculations of staffing requirements is the detailing of patient needs – and of the knowledge and skills that will be required to meet those needs – with an appreciation that there will be unpredictable variations over time (**Box 6.1**).

Patient need has many components, including:

- the severity and complexity of acute illness and chronic disease
- other physical characteristics (e.g. mobility, body weight, skin integrity, continence)
- consciousness and cognition
- mood and emotionality (e.g. anxiety, depression, motivation to engage in rehabilitation)
- the frequency and complexity of observation/monitoring and interventions
- the needs of relatives.

The staff resource includes members of the clinical team, the whole range of ancillary staff, and support services. Collectively, these personnel must be adequate to meet patient needs. This requires evaluation of:

- nursing numbers and skill mix
- interdisciplinary team skill mix, with consideration of variations in the availability of team members (e.g. doctors, respiratory/physiotherapists, equipment technicians out of hours).

The context of care is also significant, that is:

- the physical environment (e.g. the ease with which patients can be observed, whether cohorted in groups or in separate rooms)
- workload variations – peaks, troughs and overall activity in the department (e.g. admissions, discharges, transport to other areas (e.g. imaging), transfers).

Box 6.1 Standards for nurse staffing in critical care[27]

1. Critical care patients must have immediate access to a registered nurse with a post-registration qualification in the speciality.
2. Ventilated patients should have a minimum of one nurse to one patient.
3. The nurse–patient ratio should not go below 1 : 2.
4. Patients' care needs should equate to the skills and knowledge of nurses delivering and/or supervising that care.
5. Units should employ flexible working patterns as determined by unit size, activity, case-mix and the fluctuating levels of care for each patient.
6. Supernumerary clinical coordinators who are senior critical care qualified nurses will be required for larger/geographically diverse units of more than six beds. Their role is to ensure effective, safe and appropriate care, by managing and supporting staff and patients, and acting as communicator and liaison between team members.
7. The layout of beds and use of side wards must be taken into account when setting staffing levels.
8. Ongoing education for all staff is of principal importance to ensure knowledgeable and competent staff care for patients. Clinical educator posts should be utilised to support this practice.
9. Health care assistants have a key role in assisting registered nurses deliver direct care and in maintaining patient safety. These roles should be developed to meet the demands of patients and of the unit. However, the registered nurse remains responsible for the assessment, planning, delivery and evaluation of care.
10. Assistant practitioners can provide direct care under the indirect supervision of a registered nurse, who will remain responsible for the assessment, planning and evaluation of patient care. The role of assistant practitioners requires further evaluation.
11. Administrative staff should be employed to ensure nurses are free to give direct care, and to support essential data collection.

OTHER RESPONSIBILITIES

The manager is also responsible for:

- coordinated operational management of the area
- quality of nursing care
- management of nursing pay and non-pay budgets
- personnel management
- dealing with complaints and investigating adverse incidents.

There are always dynamic political, social and economic forces bearing on the organisational objectives and resources of the hospital and the ICU. The nurse manager needs to understand these factors and how they influence the delivery of patient care and the maintenance of a healthy environment for individual and team development. The manager must be able to communicate the key issues to the whole team in the form of an agreed strategy and a clear, regularly updated operational plan for the department. There needs to be a working system that addresses and integrates the views and needs of all users of the service, including patients and their families. Such a system should enable a shared understanding of exactly what needs to be done in practice, and where each team member fits into the plan.

Externally, the manager represents the service and ensures that other disciplines and the bigger organisation are informed about critical care issues.

Teams perform most effectively when individuals believe that they are working toward some common and worthwhile goals. The principles of shared governance can be usefully applied in this perspective, whereby staff collectively review and learn from their own practices. This has to be in the context of:

- the strategic agendas of the unit and the hospital
- the development of the service
- financial issues, budgets and budgetary restraints
- an appreciation of day-to-day working issues.

STRESS MANAGEMENT AND MOTIVATION

The ICU can be extremely stressful, demanding considerable cognitive, affective and psychomotor effort from staff. Supervisory and feedback arrangements should be in place to alleviate such demands, and to enable identification of staff members who are having difficulties at work. Studies of human resource practices in hospitals have found an association between the quantity and quality of staff appraisal and patient mortality, with organisations that emphasise training and teamworking having better outcomes.[28] Regular individual performance reviews and formulation of development plans provide positive assurance and encouragement, and can identify specific personal requirements such as educational needs.

Providing staff at all levels with opportunities to feel that they can influence and perhaps modify the working environment tends to decrease stress and increase motivation. Flexibility to work in different ways at different times while still meeting the overall demands of the department is important. It is the manager's job to balance and meet the needs of staff, patients and the organisation. One method is to give staff choice regarding rostering, partly to help with work–life balance, but also so that the nurse can opt to work with particular patients for a period so as to practise certain skills, and to promote continuity of care. This can have real benefits for patients.

NURSE EDUCATION

There are well-established educational programmes for critical care nurses, although the content and quality vary. There is a role for study of relevant

Box 6.2 Critical care competency framework[29]

Key competencies for critical care nurses education

- Respiratory system, e.g. safe, effective, appropriate nursing management of patient requiring invasive ventilation, using a range of suitable ventilatory modes, pulmonary recruitment manoeuvres (e.g. prone positioning), strategies for weaning, consideration of patient comfort (sedation, etc.)
- Cardiovascular system, e.g. safe, effective, appropriate nursing management of patients suffering from cardiovascular instability, including acute coronary syndromes, cardiac dysrhythmia, haemodynamic instability secondary to other factors, circulatory failure, peri-arrest situations, cardiopulmonary arrest
- Renal system, e.g. safe, effective, appropriate nursing management of patients with acute kidney injury, including fluid and drug therapies, urinary drainage devices, renal replacement techniques
- Gastrointestinal (including liver and biliary) system
- Neurological system
- Integumentary system

Other essential areas

- Medicines management
- Admission and discharge
- End-of-life care
- Rehabilitation
- Psychosocial well-being
- Communication and teamwork
- Infection prevention and control
- Inter- and intra-hospital transfer
- Evidenced-based practice
- Professionalism
- Defensible documentation
- Leadership

philosophy, nursing theory and research methods, but the fundamental requirement is for learning that focuses on clinical practice and practical problem solving (**Box 6.2**).

A competency framework can be used to structure descriptors of the skills, knowledge and attitudes needed to achieve specific patient outcomes. There needs to be consideration of both how individual actions are integrated into holistic care, and the role of independent clinical judgement. Developing nurses' critical thinking and decision-making skills are also important. Appraisal of learners' performance requires assessors to observe and question the nurse in practice; although this places significant demands on hard-pressed clinical areas. It may be that high-fidelity simulators can be used to test performance away from the practice setting in future.

Frameworks to identify different levels of performance have been developed – for example, based on Benner's novice-to-expert hierarchy (**Table 6.1**). UK critical care nursing organisations have described a three-stage version of the model; novice critical care nurses should spend up to 12 months acquiring the core competencies under supervision, then undertake a formal course of training (stage 2), and finally progressing to practice without direct supervision (stage 3).[29]

CRITICAL CARE NURSING RESEARCH

Critical care services treat small numbers of patients at high cost. Critical care has great physical and psychological impact, but often uses somewhat untested methods. Patient outcomes are influenced by different organisational approaches, staff characteristics, varied working practices and treatment methods, as well as differences between patients themselves. Therefore, a range of quantitative and qualitative investigative procedures is needed to gain an understanding of the issues. The approach chosen depends on the nature of the research question, and also the objectives of the researcher and the resources available.

REVIEWING RESEARCH

The methods used to appraise research depend partly on the type of work under review. The following questions may help clarification:

- *Justification for the research:* are the background and rationale of the study clearly established?
- *Scientific content:* is there a specific question/hypothesis?
- *Originality:* is it a new idea, or re-examining an old problem differently or better?
- *Methodology and study design:* are the methods appropriate and are they likely to produce an answer to the question? For example:
  - comparisons of different treatments generally require quantitative measurements of particular end-points (e.g. the dose of a drug needed to achieve a target physiological variable)
  - understanding how an individual thinks or feels usually involves analysis of qualitative material (e.g. data from interviews with patients and families).
- Is the research method described in a way that can be readily understood, and replicated?
- Are the relevant results shown? Are data given that provide details of the individuals under investigation and details of how representative these might be of a larger population?
- Is the analysis appropriate and is the power of the study adequate? (This is determined by the numbers involved and the size of the difference being examined.)
- Interpretation and discussion: are the conclusions and comments reasonable in the light of the results? Do the conclusions follow from the analysis?
- Are any references to background literature comprehensive and appropriate?

Table 6.1 Assessment of critical care nurses' performance (*after* Benner[3])

RATING	DEFINITION	OBSERVED BEHAVIOUR	PROMPTS
Novice	Limited skill and/or knowledge, inconsistent practice, variable interpersonal skill Limited understanding of wider context, inflexible rule-governed behaviour	Lacks coordination and confidence Potential for omissions or inaccuracies Unable to demonstrate accurate and safe performance despite repeated attempts	Requires frequent directive prompts, supervision and advice
Advanced beginner	Some skill and knowledge, generally consistent practice and interpersonal skill; variable ethical thought Some appreciation of situational influences	Coordinated and confident in fundamental tasks Easily distracted or unable to integrate other aspects of patient care	Requires occasional directive prompts and some supervision
Competent	Consistent safe, accurate and effective practice, interpersonal skill and ethical thought Conscious and deliberate planning with consideration of immediate context	Skilful, confident and coordinated patient-focused practice, with evident integration of other aspects of care Prioritisation of workload	Self-directing without supervision
Proficient	Consistent safe, accurate and effective practice, higher-level interpersonal skill and ethical reasoning Conscious and deliberate planning with consideration of longer-term goals Adapts care in response to changing situations	Skilled and accomplished practice, proactive and flexible approach to care Problem solving and decision making through reflection Role model	Capable of supporting and demonstrating skills to others

- What can be taken from the study – that is, what value does the study have in terms of supporting or developing clinical practice?
- What is the overall impression of the work? Is it credible? Is the presentation clear and informative?
- If evaluating a paper, has the work undergone proper peer review?

UNDERTAKING A RESEARCH PROJECT

STAGE 1: IDENTIFY AND CLARIFY THE TOPIC TO BE EXAMINED

Research is most valued when it is relevant to practice. The researcher is more likely to gain support for investigation of high-risk and high-cost processes. Many everyday methods and treatments warrant examination too, particularly when there are significant variations in practice. The researcher should determine how the topic of interest might be described in a measurable way, and formulate the investigation as a question, with consideration of how answers can be obtained.

STAGE 2: GATHER RELEVANT BACKGROUND INFORMATION

It is important to collect information that enables an understanding of the issues under investigation, and helps justify performing the study. Hospital libraries are useful, not least because there may be staff members who can give advice about the project. Indexes for journals and books are in print- and computer-based formats, with databases and texts also available through the internet. A good starting point is Google Scholar (http://scholar.google.co.uk//). This uses a broad approach to locating articles across many disciplines and sources. Specific medical/nursing websites include:

- PubMed, from the US National Library of Medicine (www.nlm.nih.gov/), with access to the MEDLINE (Medical Literature, Analysis, and Retrieval System Online) biomedical database
- the Cumulative Index to Nursing and Allied Health (CINAHL) at www.ebscohost.com/biomedical-libraries/the-cinahl-database
- the Cochrane Collaboration of systematic reviews of health care interventions (www.cochrane.org)
- EMBASE (www.embase.com/), which is particularly good for pharmacological information.

The researcher must also evaluate the quality of the information gathered. Different types of research are traditionally held to have different weights (e.g. results obtained from randomised controlled trials are considered to be high-grade evidence, whereas observational studies are deemed less useful). This hierarchy is not always applicable and may devalue some valuable work, but it does emphasise the need to critically examine the credibility of research.

Box 6.3 Issues for consideration in the review of research proposals

Particular to the patient/research subject

- The possibility of risk of harm
- The degree of inconvenience to the patient/research subject (or associated persons, e.g. patients' relatives)
- The duration of the study period (for the patient/subject)
- Whether the individual patient or research subject may obtain a direct or indirect benefit from participating
- The characteristics of the population to be studied
- Inclusion and exclusion criteria, and the rationale for inclusion and exclusion
- Whether any of the patients/research subjects are enrolled into other research projects that could influence the new study

Particular to study design/integrity

- The credentials of the researchers
- Whether the researchers are subject to any conflicts of interest
- The benefits of the research balanced against its detriments
- What is needed to fund and resource the study
- Whether there is an effective mechanism for managing adverse events
- Whether there is an effective mechanism for terminating the study
- The frequency of occurrence of the phenomenon to be studied
- The duration of the study
- The feasibility of recruiting sufficient patients or research subjects to meet statistical power requirements
- Where, when and how patients or research subjects are to be recruited, and who will be doing the recruiting
- How long the patient or research subject will be given to decide whether or not to take part
- What happens if the patient agrees to take part but subsequently wishes to withdraw
- How data will be collected, scrutinised, stored – and subsequently disposed of – in order to protect patient confidentiality
- Whether the research is analysing an established procedure or a novel method

STAGE 3: DESIGN A METHOD THAT:

- will provide data that will answer the question
- is adequate to answer the question (e.g. studies that use statistics require consideration of the numbers of data items needed to demonstrate differences between different groups or categories)
- is feasible to do in practice
- is ethical.

STAGE 4: COLLECT THE DATA

This is relatively simple provided that the data items to be collected are clearly defined. A common pitfall is to collect lots of unnecessary data and lose the focus of the original question. Data should be collected in a manageable format/database.

STAGE 5: ORGANISE THE DATA

By this stage, a large amount of material may have been gathered. It is important that:

- a system of categorisation and analysis is used that meets the objectives of the investigation
- the analysis addresses the original question
- appropriate statistical methods are used (specialist advice may be required).

STAGE 6: PRESENT AND EXPLAIN THE DATA

Presentation can take many forms, but it is always necessary to:

- set out the question asked
- describe the research method so that it is clear what was done
- illustrate the results and their analysis and
- present the key findings and conclusions.

The conclusions should follow from the analysis without inappropriate extrapolations. Any applications to clinical practice should be highlighted. The report must be presented succinctly and in a constructive manner, but with any shortcomings or problems in the study acknowledged. The goal is that the reader can understand the methodology and how the results were interpreted, as well as any limitations of the work. The main point of research is to share what has been learnt.

STAGE 7: EVALUATE THE PROJECT

The final phase is reflective. Conducting research is a process that can always be improved. Constructive feedback from colleagues should be sought. The researcher should review what has been learnt from the process as well as from the results of the study, and consider how the work might be further developed in the future.

RESEARCH ETHICS

The practitioner must always consider the ethical issues associated with conducting research. It may be

necessary to submit an application for approval to an ethics committee. There are local differences in the process of obtaining ethical approval for research on humans, but most systems incorporate the principles of the Declaration of Helsinki (see the World Medical Association website at www.wma.net/en/30publications/10policies/b3/index.html). The ethics committee looks beyond the stated necessity and significance of the proposed research to evaluate a range of matters particular to the patients who may be involved, and to aspects of the study design. Some of these issues are summarised in **Box 6.3**.

7

Ethics in intensive care

Raymond F Raper and Malcolm M Fisher

DEFINITION

Ethics is the study of how one ought to behave. In contrast, the law defines how one must behave to avoid punishment. Ethics is concerned with differentiating right from wrong behaviour. For most people, a sense of ethics is innate. Medical ethics particularly relates to the relationships between health care practitioners and patients and is not limited to doctors even if it is particularly applicable to doctors. Ethical conflict almost always involves a clash of values and appropriate resolution depends on recognition of the conflicting interests and values.

ETHICAL FRAMEWORK

Medical ethics are usually discussed in the context of principles. These principles inform ethical behaviour and can be summarised as:

1. *Autonomy*: the principle of individual self-determination in respect of medical care
2. *Beneficence*: the principle of 'doing good', an obligation always to act in the best interests of patients with respect to saving lives, curing illness and alleviating pain and suffering
3. *Non-maleficence*: the principle of doing no harm
4. *Fidelity*: faithfulness to duties and obligations, a principle underlying confidentiality, telling the truth, keeping up with medical knowledge (i.e. continuing professional development) and not neglecting patient care
5. *Social justice*: the principle of equitable access of all citizens to medical care according to medical need
6. *Utility*: the principle of doing most good for the most number of people – that is, achieving maximum benefits for society without wasting health resources.

Utility is a consequentialist concept, where the right or wrong of an action is determined by the outcome rather than by an a priori principle. The 'correct' action may thus vary with the particular circumstances. This is sometimes seen as an entirely different framework from the rights or principles-based system. The utility principle is more applicable to systems development in medical practice and may create conflict with responsibility for individual patients. It is important that intensivists participate in the public debate that determines how much of society's goods are to be allocated to medicine and how much of the health budget is to be allocated to intensive care without, at the same time, surrendering responsibility for the interests of individual patients. Moving between these collective and individual spheres of functioning can be challenging, but is essential to good medical practice.

Ethical conflict is most often encountered where there is a clash of values. Rationing, for instance, involves a clash between the values of individual rights and collective rights. Euthanasia usually involves a clash between the values of sanctity of life and autonomy. Resolution of ethical conflict depends on recognition both of the values that are in dispute and of the principles that are operative. Absolutist terms such as 'futility' tend to mask the values-in-clash and are thus unhelpful in resolution of ethical conflict. Consideration of the various interests involved is also helpful in foregrounding the real issues behind an ethical conflict.

ICU ETHICAL PROBLEMS

END-OF-LIFE MANAGEMENT

During its relatively brief history, intensive care has seen a dramatic increase in both capacity and capability. Practice has become codified and at least partly standardised and intensive care is more generally accessible. Greater emphasis on individual rights has seen an increased demand for medical resources in general and this has flowed on to intensive care. The great challenge for intensive care lies in the reality that prolonged life support is often quite easily achieved without there being either inevitable recovery or intractable demise. Of the sickest patients in the intensive care unit (ICU), only a proportion ultimately recovers and can be returned to a reasonable quality of life. Even this would not be a problem were it possible to predict survival with any degree of certainty and a great deal of effort has been expended in an attempt to achieve this. Unfortunately, this has met with only limited success and consideration of the appropriateness of ongoing intensive care is necessarily conducted against a background of prognostic uncertainty.[1]

In consequence of this, death in ICU usually involves some limitation or withholding of life-sustaining treatment.[2,3] This has now been well documented in many studies from around the world and the driving factors are now reasonably well understood.[2–9] The ethical principles underpinning this practice are those described above. Intensive care is inevitably burdensome and requires a commensurate benefit to conform to beneficence and non-maleficence. Although life itself has a value, this is considerably offset if it is brief, painful and non-interactive. As death becomes increasingly imminent, its deferment at any cost becomes less appropriate. Considerations of justice should rarely intrude at the bedside. However, prolongation of life by artificial means in a patient with little or no chance of survival may challenge the rights of survivable patients to limited intensive care resources.[10] Where resources are publicly owned, offering to one patient treatment that cannot be made available to all patients in similar circumstances is fundamentally unethical. The collective has the ethical right to regulate access to even beneficial therapy provided it does so in a non-discriminatory fashion. The intensive care specialist does not have a right to unilaterally apply or withhold resources against the will of the collective. Unfortunately, the will of the collective is rarely known.

End-of-life management in the intensive care setting has been subjected to a considerable research endeavour over the past several years.[2,4,11–13] Insights that can be gleaned from published studies include:

- Patients not infrequently die in some discomfort in ICU receiving unwanted therapy.
- Considerable dissatisfaction has been reported by both patients and families with management at the end of life.
- Patients' wishes with respect to end-of-life treatment are commonly unknown.
- Patients and families may be quite ignorant of the nature and prognosis of end-of-life initiatives such as cardiopulmonary resuscitation.[14]
- Active interventions including obligatory, outside consultations have not been particularly effective in improving the quality of end-of-life management.
- There is a good deal of practice variability across countries and communities with respect to attitudes to death, dying and the withholding and withdrawing of active treatment.[2,8]
- The reported variability in practice relates to attitudes of doctors and nurses, decision-making processes and to actual practices once a treatment-limiting decision has been made.
- Although some form of treatment limitation is common, withdrawal of treatment is not practised and is even illegal in some communities, whereas active foreshortening and active euthanasia are reported in others.
- Some confusion remains over the distinction between active foreshortening of life and administration of drugs that both relieve unwanted symptoms and shorten the dying process. The nature and doses of agents used to shorten life actively are not necessarily different from those used to relieve symptoms without the intention of accelerating death, and the time to death may also not be affected.[2]
- Most patients and families report a preference for some form of collaboration in end-of-life decision making.[15–17]
- Involvement in decision making is burdensome for families and can be associated with long-term sequelae.
- Clinicians are now frequently involved in the delivery of care they consider inappropriate. This poses a risk of moral distress and consequent burnout. Inappropriateness involves a very subjective assessment and better reflects the organisational culture of the ICU than patient characteristics.[18]

PRACTICAL CONSIDERATIONS

- Decisions to limit treatment in ICU depend on a careful consideration of the burdens and benefits of treatment.
- Prognostication in ICU practice is imperfect so that decision making is often based on probability rather than certainty. This has led to formulation of concepts such as 'practical certainty'.[19]
- Decision making is usually an evolving process, commonly involving several discussions of therapeutic possibilities, quality of life and patient preferences.[9,11]
- Competent patients should always be involved in discussions, and inclusion of family members should be encouraged and fostered.
- Given the common desire for collaborative decision making, seeking patient preferences and consensus in a proposed management plan is more appropriate than either surrendering decision-making responsibility to patients or surrogates or systematically excluding patients and/or carers.
- The important role of nurses and allied health practitioners in the management of critically ill patients warrants respect by inclusion in discussions. Failure to do so has resulted in nurses inappropriately taking unilateral, surreptitious action justified as patient advocacy. Legal action for unlawful termination of life has also resulted.

ADVANCE DIRECTIVES AND POWER OF ATTORNEY

Patients may formally signal their preferences for end-of-life care in a written document or may nominate a surrogate decision maker in the event of future incompetence. The legal standing of such documents is highly variable. Nevertheless, as expressions of self-determination they have considerable ethical validity

and warrant respect. Unfortunately, advance directives are often insufficiently specific and it is not always possible to be sure that decisions included in such documents were fully informed and rational. Given the frequent reticence of patients to consider end-of-life matters,[14] advance directives are unlikely to become widely pervasive.

EUTHANASIA

This term is strictly applicable only to situations of active termination of life with the knowledge of and usually at the request of a patient suffering a terminal and/or debilitating, incurable illness. Physician-assisted suicide is a variation of this practice. This is a subject of considerable debate and is now legal in a small number of jurisdictions though probably practised surreptitiously in many more. Ethicists, largely on consequentialist grounds, maintain no distinction between this and the terminal withdrawal or withholding of treatment[20] (sometimes inappropriately termed 'passive euthanasia'). For intensive care practice, however, the distinction seems obvious and essential. The distinction is most often argued on the basis of intent. Although there may well be a difference in intent between active euthanasia and withdrawal of treatment, relief of pain and suffering may be at the heart of both activities. Even if this is the case, active euthanasia in the ICU context is generally a disproportionate means to the end. Treatment limitation is, arguably, an essential component of intensive care practice whereas euthanasia is not and there is usually a clear and obvious difference in the acts themselves. Thus although it may be true that in some instances there is no moral distinction between euthanasia and withdrawal of treatment, this does not mean that there is never such a distinction.

TREATMENT WITHDRAWAL

- Once a decision has been made to withdraw or withhold treatment, the decision, the participants, the rationale and the details of the treatment limitation should be clearly documented in the patient records. Surreptitious treatment limitation is difficult to justify and potentially hazardous.
- There is no moral hierarchy of treatments, but ventilator withdrawal is more obviously terminal than, say, withdrawal of renal replacement therapy or antibiotics.
- Although treatment may sometimes be withdrawn or withheld in ICU, care must never be withdrawn. An alternative, palliative management plan focusing on symptom relief and patient dignity should be documented and instituted.
- From a practical perspective, progressive treatment withdrawal enables progressive management of any resultant discomfort. It also helps foster an appreciation that death is a consequence of disease or organ system failure rather than of the withdrawal of treatment.
- Symptom relief, especially with sedatives and narcotics, may sometimes appear to hasten death. This is often justified on the 'double effect' principle, as the acceleration of death though foreseen was not intended. More relevantly, however, this can be seen simply as a trade-off of two aims where the relief of unwanted symptoms assumes a higher priority than avoidance of the foreshortening of life. Certainly, it is difficult to justify unnecessary pain and suffering at the end of life on ethical grounds. Finally, clinical experience suggests that, rather than shortening life, narcotics and sedatives commonly prolong the dying process by reducing cardiovascular stress.

CONSENT

Informed consent lies at the heart of the doctor–patient relationship and has both ethical and legal implications. Consent relates both to treatment (especially to invasive procedures) and to participation in research. General principles relating to consent can be listed:

- Patient consent is a fundamental tenet of medical practice. Routine or minor procedures may be included in the general consent to treatment.
- Consent may be waived in an emergency for treatment that is immediately necessary to save life or avoid significant physical deterioration. This applies whether or not the patient is technically competent.
- Valid consent is dependent on the provision of adequate information, including benefits and risks, and must be voluntary and free from coercion.
- Written consent provides evidence of the consent process, but consent itself need not be in writing, unless specifically required by a local authority.
- Competent patients are entitled to refuse consent to treatment even when doing so may result in harm or death.
- Surrogate consent for more elective procedures relies for ethical justification on the principle of autonomy. Patients' interests must thus be paramount. Legal requirements relating to surrogate consent are highly variable and 'surrogate' is often formally defined and limited by local statute.
- Autonomy also provides the ethical justification for advance directives, the legal status of which is also highly variable.
- An enduring power of attorney generally applies to financial affairs rather than to consent to treatment. Again, self-determination constitutes the ethical basis.
- Competent minors may or may not have a legal right to consent, but age does not affect ethical considerations independently of insight and understanding. Even incompetent minors have some entitlement to confidentiality and all are entitled to protection from harm, even if that harm devolves from parental or

guardian decisions based on well-meaning conviction or prejudice.
- Consent is especially required to involve a patient in research, where the importance of full disclosure is even greater. Medical research imposes some particular ethical issues, to be discussed below.
- Consent is also required for teaching purposes, such as video recording and photographing patients and teaching practical procedures.
- There may be a legal requirement for consent for testing for diseases such as human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) and hepatitis. These diseases are not especially unique from an ethical perspective, however, and patients' rights to privacy are not absolute.

Because intensive care patients are often unable to provide formal consent and because critical illness itself may negate the preconditions for consent, this issue is commonly neglected. Consent to 'routine' or everyday procedures in critically ill patients is often presumed or rather subsumed under the general consent to treatment. Near-universal consent is possible, however.[21] The precise role for consent in the intensive care context has not been fully defined, but deviations from the general requirement for consent require some justification. The legal requirement for consent varies with different interpretations and jurisdictions. If taken to extreme, such as enabling surrogate refusal for 'routine' procedures such as central venous access, consent-related autonomy may become incompatible with the beneficence and non-maleficence principles and may largely become untenable.

RATIONING AND SOCIETAL ROLE

Intensive care is, by nature, expensive. This creates a tension and a potential ethical conflict for intensive care practitioners. It is essential to find a balance between responsibilities to individual patients and those to the collective. In theory, this is achieved by removing all rationing decisions from the bedside. Established norms rather than temporal availability or personal influence should determine access to ICU. Treatment is withheld or withdrawn not because there is a 'more deserving' patient at the door but because it would always be withheld or withdrawn under the particular clinical circumstances. Wide variations in access to medical care for similar patients across a single society cannot be ethically justified. More challenging is the definition of society. If a sufficiently broad perspective is adopted, most intensive care is difficult to justify. The ethically responsible intensive care practitioner will both advocate for individual patients and participate in the mostly unstructured social debate that determines what proportion of community resources is expended on medicine and on intensive care in particular.

PROFESSIONALISM

Medical practitioners occupy a unique and, usually, a privileged position in society. With this come a number of responsibilities. These are generally well covered in codes of conduct issued from time to time by professional societies and institutions of learning. The oldest and perhaps best known is the hippocratic oath. Professional, ethical responsibilities may be sorely tested where the well-being of the practitioner is at risk from medical practice, as with infectious disease epidemics and acts of terrorism. Resolution of this potential conflict has not been satisfactorily determined to date.

Among the ethical responsibilities of medical practitioners are:

- maintenance of professional standards by continuing education and professional development
- maintenance of appropriate professional relationships with patients
- appropriate documentation of medical interactions
- participation in quality and safety initiatives and practices
- respect for patient and staff confidentiality
- respect for the tenets of the law.

INDUSTRY AND CONFLICT OF INTEREST

Relationships among doctors and the medical technology and pharmaceutical companies are complex.[22] Doctors and industry are somewhat interdependent. Medical advances do not occur in a vacuum and the invention, assessment, development and marketing of new drugs and technologies necessitate close relationships between doctors and industry. Although doctors are entitled to fair consideration for their skills and effort, the relationships must be overt and openly scrutinised if conflicts of interests are not to occur. The nature of the rewards offered by companies for medical involvement in product development is diverse but includes both direct and indirect payments. The economic justification for all these payments depends on their effects on subsequent product marketing. The propriety of travel and related support is questionable unless it is directly and attributably related to openly contracted services. Involvement of companies with vested interests in pseudoeducational initiatives and even guideline development may be little more than covert marketing.[23] Some open labelled research initiatives with large, practitioner reward programmes are similarly worrisome. Initiatives designed to limit these conflicts of interest include open disclosure of all financial relationships and voluntary and involuntary codes of conduct on both sides of the relationship. Financial inducements can be easily concealed, however, and specific financial relationships can be obscured by their volume and pervasiveness. Although this potential for ethical conflict exists in many other commercial relationships, the nature of medicine and the associated

expenditure of, often, public funds dictate that this is not an entirely private consideration.

RESEARCH

Critically ill patients can rarely consent themselves to participation in research projects and yet they are able to benefit from the results of earlier studies with similarly problematic consent issues. Locating surrogate decision makers within a timeframe appropriate for some types of research can also be impossible. This has been recognised and enacted in a consent waiver for even randomised clinical trials. The potential ethical conflict in this situation lies in the use of a patient as an instrument to achieve another's end without express consent. There is a potential 'slippery slope' in valuing the rights of the collective over those of the individual, and yet the individual can be seen to have an interest in the resolution of some of these important clinical questions. The conduct of such research must be carefully scrutinised by outside agents and careful consideration must be given to the balance between risk and benefit. A potentially greater benefit might help justify a potentially greater risk even if the benefit might not be directly applicable to the subject. Studies of, for example, disease mechanisms involving little or no potential direct patient benefit would need to involve no material risk. In general, the principles of consent detailed above are applicable. When a waiver is applied, patients and/or surrogates should be afforded an opportunity to withdraw from the study at the earliest opportunity.

ORGAN DONATION

Concern has been raised over possible or apparent conflict of interest with ICU practitioner involvement in organ donation. This has become especially at issue with the worldwide drive to increase donation for transplantation and the re-emergence of donation after death established on circulatory criteria. The ethical problem, as for research, lies in the use of one patient for the benefit of another or of society in general. The ethical justification for donation depends, again, on autonomy as most citizens when asked express a willingness to be involved in posthumous donation for transplantation. Provided that the focus remains on the patient's interests (including the fulfillment of the known or projected wishes of the patient and the sensitive care of their family), there is no real ethical conflict intrinsic to the involvement of ICU practitioners in the donation process. More and more, donation is being enacted as part of appropriate end-of-life management and is thus easily justified.

RESOLVING ETHICAL CONFLICT

Ethical conflict most commonly arises where there is a clash of values or interests. Resolution is often difficult because of entrenched positions and convictions. The innate sense of right and wrong lends itself to strong convictions in a way not seen in other human activities. The fundamental basis of resolution is discussion, enabling exposure of the values or interests that are in conflict. This may require a third party or mediator. Absolutist convictions such as 'sanctity of life' and absolutist terminology such as 'futility' impede conflict resolution and have to be unravelled.

Actual and potential conflict can frequently be resolved during end-of-life discussions. When this is not possible, outside mediation may be beneficial. The precise utility of this is difficult to establish but it is likely to be most beneficial if initiated early. Ethics committees have an important role in establishing frameworks for ethical practice. There is some evidence that formal ethics consultations facilitate end-of-life management, but the principles utilised are those of open discussion and full disclosure and these should characterise all bedside communication.

Recourse to legal processes may be essential, especially where an impasse has developed and families insist on continuing management felt inappropriate by care givers. There has been a small number of cases where the legal system has been able to respond swiftly and to cope quite well with the complexity of medical decision making, although this is not always the case. It is likely that conflict over end-of-life decision making will increase, particularly in multicultural democracies, and that court intervention will become mere routine rather than a last resort in the face of communication failure.

There are several useful guidelines informing practice, particularly in relation to end-of-life decision making. Individual practitioners should be aware of these and adapt them to local circumstances. Institution-based guidelines that conform to more overarching documents are probably most useful. Most learned colleges and professional societies now promulgate such practice guidelines in various forms.

Common problems after ICU

Carl S Waldmann and Evelyn Corner

Until recently, an intensive care unit (ICU) stay was deemed successful if a patient survived to go to the ward. No consideration was taken of the patient dying on the ward or soon after leaving hospital, or indeed if the patient went home with an appalling quality of life.

Mortality figures for patients leaving our own ICU recently are shown in **Figure 8.1**.

A Kings Fund report in 1989 concluded that it was necessary to look at the morbidity following critical illness as well as mortality: 'There is more to life than measuring death'.[1]

Publications such as that of the Audit Commission (Critical to Success)[2] and that of the National Expert Group[3] (Comprehensive Critical Care) have supported the development of follow-up for patients following a stay in intensive care. In 2009 the National Institute for Health and Clinical Excellence published its guidance and recommendations to facilitate the introduction of rehabilitation programmes in all hospitals looking after critically ill patients.

In Reading, a follow-up programme has been ongoing since 1993. Until recently the rehabilitation of patients after a critical illness has fallen between too many stools. Following multi-organ dysfunction, it is difficult to categorise a patient to an individual specialty such as cardiac, respiratory or the stroke rehabilitation teams. Family doctors often have difficulty taking on the complexity of these patients, with the result that they are denied vital advice and assistance and lack an advocate with 'teeth' to ensure timely help.

SETTING UP A FOLLOW-UP SERVICE

Funding such a follow-up programme has posed local problems in many trusts. The service in Reading was initially approved and funded by local, then regional, audit committees.

The service is staffed by a follow-up sister who spends most of her time in this role helped by a staff nurse and an ICU consultant for the clinics held as a formal outpatient clinic 2–3 times monthly.

Invitations to patients who were in ICU were initially extended to all patients that had been in the ICU for more than 4 days; they were and are seen in clinic at 2 months, 6 months and 1 year after discharge and occasionally, but with time the invitation was extended to patients who have been in ICU for a shorter time period. Referrals are also sent from other hospitals where follow-up wasn't happening. It is important to identify clerical and IT support, and to achieve good collaboration with other hospital departments and general practitioners (GPs) to ensure patients do not make unnecessary journeys to the hospital, by trying to coordinate the patients' visits and ensuring that transport is organised where necessary. Very often, patients will voluntarily come from long distances if they had initially been admitted from other geographical locations – out-of-area transfers.

The logistics of running the service include arranging specific tests that may be required for the visit, such as pulmonary function tests and blood/urine for creatinine clearance. There may be special tests such as magnetic resonance imaging (MRI)[4] for patients who had a tracheostomy during their stay in ICU.

The service in Reading costs £30 000 annually, which, in the context of the bigger picture (£4.5 million budget for our ICU), is a small price to pay (**Table 8.1**). An unexpected bonus is that the clinic is often seen by the patients as a convenient place to make donations to the ICU.

Recently the clinic visits have been funded exactly the same as any other outpatient appointment attracting about £160 for the first visit and £80 for subsequent visits.

SPECIFIC PROBLEMS POST-ICU

The range of problems seen after intensive care is vast and ranges from nightmares and sleep disturbance through to ill-fitting clothes. Many of the problems are very specific to the individual but there are also recurrent themes. Flashbacks are common, as are taste loss, poor appetite, nail and hair disorders and sexual dysfunction.

There are several quality-of-life tools used in follow-up studies (**Box 8.1**).[5–9] Objective measurements may be inappropriate because they look at aspects such as return to work; often, patients in their 50s may not return to work after a traumatic episode, including ICU, and subjective measures would be more applicable, such as Perceived Quality Of Life (PQOL).

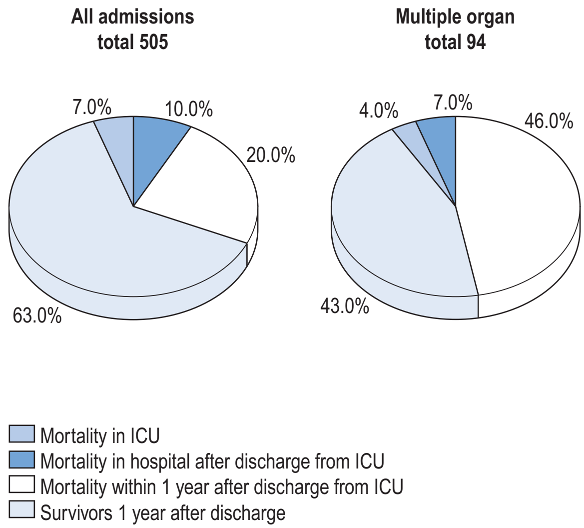

Figure 8.1 Mortality rates for leaving the intensive care unit (ICU).

Table 8.1 Costs of running a service

FOLLOW-UP CLINIC	COST (£)
Nursing	18000
Medical	6000
Administration	4000
Laboratory tests and X-rays	2000
Total	30000

TRACHEOSTOMY

Since percutaneous techniques performed by intensivists started to replace surgical tracheostomy in 1991, we have seen an increasing number of patients tracheostomised earlier in their ICU stay.

The long-term sequelae have been assessed by lung function tests, nasoendoscopy and MRI screening (**Fig. 8.2**). There are minor cosmetic problems, such as tethering (**Fig. 8.3**). Tethering is easily dealt with in ear, nose and throat outpatients under local anaesthetic.

More difficult to manage is tracheal stenosis, defined as a 15% reduction in tracheal diameter. However, there

Figure 8.2 Assessment of long-term sequelae.

Figure 8.3 Tethering.

have only been two cases to date. These were seen in the first series of 30 cases.[4]

MOBILITY

Even in the absence of trauma, patients can expect to need 9 months to 1 year to regain full mobility. This is usually due to a mixture of joint pain, stiffness and muscle weakness. In one study[10] the duration of ICU stay was associated with mobility problems probably associated with loss of muscle mass. If questioned, patients will often report climbing stairs on all fours and descending on their bottoms (**Fig. 8.4**). Muscle wasting can present as a severe localised problem.

This may be associated with critical illness polyneuropathy (CIP),[11] which not only prolongs ventilatory weaning but also frequently both complicates and

Figure 8.4 Climbing and descending stairs.

delays rehabilitation. Muscle relaxants have been implicated in the development of CIP[12] but have not been shown to cause statistically significant increases in time to wean from ventilation and duration of stay in ICU.[13]

Until recently, there have been no specific rehabilitation programmes for patients recovering from critical illness, although rehabilitation programmes for heart attack, stroke and respiratory disease are well established. A three-centre study has shown that a self-help physiotherapy-guided rehabilitation exercise programme will speed up physical recovery after intensive care.[14]

It is important occasionally for a member of the team to try to spend time with patients at their homes to assess their special needs and liaise with the GPs, district nurses, community physiotherapists and occupational therapists.

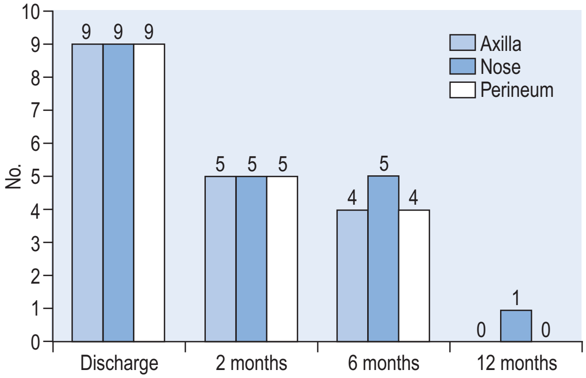

Figure 8.5 Colonisation with meticillin-resistant *Staphylococcus aureus* (MRSA).

SKIN

Patients complain of a variety of non-specific disorders, including hair loss and nail ridging. Severe pruritus used to be common and not amenable to treatment and was traced back to the use of high-molecular-weight starch solutions in ICU. Described in 2000,[15] in 85 cardiac surgical patients, pruritus was absent in the 26 patients who did not receive starch, but there was a 22% incidence in the 59 patients who did receive starch. This is now supposedly less of a problem with the newer starches.

Colonisation with MRSA used to be common after intensive care and often persisted for up to 9 months or longer (**Fig. 8.5**). It was common to hear that patients were being treated as 'lepers' by their own family.

SEXUAL DYSFUNCTION

Any patients who estimate their sex-life activity to be less active than before ICU admission are deemed to have sexual dysfunction.

In a group of 57 patients in one study[16] there was a 39% incidence of sexual dysfunction, although 4 patients' sex life had improved. Sexual dysfunction improves with time, from a frequency of about 26% at 2 months post-ICU down to 16% at 1 year.[17] Sexual dysfunction is often thought to be a psychological problem but, interestingly, following severe burns it has been reported that there is no correlation between the incidence of post-traumatic stress syndrome and sexual dysfunction.[18] Nevertheless, withdrawing sexual intimacy because of fear of failure can damage

relationships. Often sexual dysfunction may go untreated because people are too embarrassed to mention the problem when they have recovered from a life-threatening illness.

Sexual dysfunction affects both men and women. In men it usually manifests itself as impotence or inability to maintain an erection sufficient for satisfactory sexual activity. For management guidelines for erectile dysfunction, see Ralph & McNicholas.[19]

In investigating sexual dysfunction, it is important to eliminate causes such as the use of drugs (e.g. L-dopa and H_2-blockers) and certain types of surgery (aortic aneurysm) or trauma/radiotherapy to the pelvic region. The patients may be diabetic.

Treatments available include intracavernous or transureteral alprostadil or oral Viagra. Patients with cardiovascular dysfunction have to be carefully assessed before being given Viagra. Non-pharmacological therapies include the use of vacuum devices and inflatable penile prostheses.

In females, sexual dysfunction may occur due to surgery or trauma to the pelvis. More commonly, there is a reduction in desire. Various lubricating gels can be used. As yet, the role of Viagra for women has to be determined. In 127 patients asked to fill in a questionnaire while attending the clinic, the incidence of sexual dysfunction was 45%.[20] There was no link with gender, but there was a close association with post-traumatic stress disorder (PTSD).

OTHER PHYSICAL PROBLEMS

A variety of other problems have been seen during follow-up:

- *visual acuity:* particularly in patients who have been profoundly hypotensive, visual problems may occur. Occasionally ischaemic changes may be seen on fundoscopy (**Fig. 8.6a**), which may be amenable to laser therapy (**Fig. 8.6b**)
- *facial scarring:* where the tape securing the endotracheal tube has been too tight; this scarring can affect the whole thickness of the cheek
- *unneccessary medication:* frequently medication started in ICU as a temporary measure may have been continued (e.g. amiodarone started for sepsis-related arrhythmias).

PSYCHOLOGICAL PROBLEMS

Most patients admitted to ICU have no warning of their admission (emergency admission) and these are the patients who are very much at risk of psychological sequelae post-ICU.

The majority of patients do not have a structured memory of their ICU stay. Those who do may have upsetting memories, which may be relatively innocuous, such as being thirsty and hearing a can of Coke being opened, or of a far more profound nature.

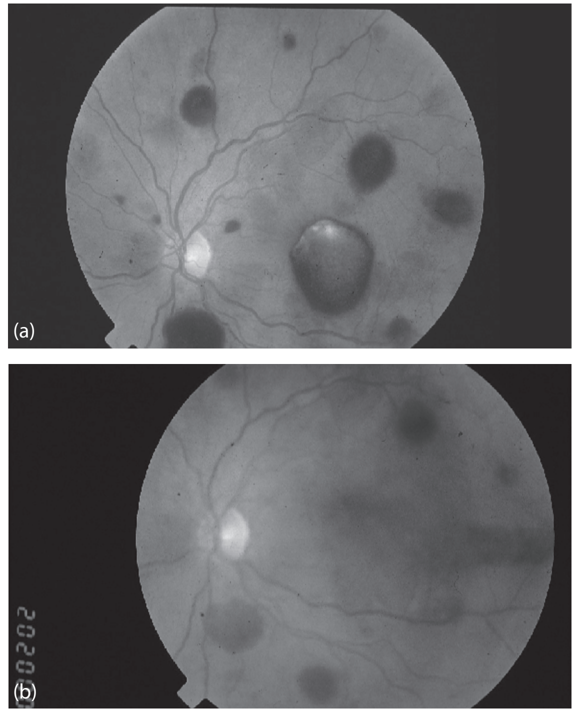

Figure 8.6 (a, b) Ischaemic changes in fundoscopy.

The story of ‘torture’ experiences is not unusual when you talk to an ex-ICU patient. The psychological impact of the experience may be formidable and may be resented by the patient. The memory of hearing that a patient is about to be ‘bagged’ was interpreted as being put into a body bag rather than a physiotherapy manoeuvre and the use of a tape measure was interpreted as being measured for a coffin and not as part of the cardiac output measurements. Previous studies demonstrate a high incidence of anxiety, depression and post-traumatic stress.[21] It is common for patients to have memories of being trapped, of being unable to move easily, of being unable to see what is happening and of feeling intensely vulnerable. The anxiety of impending death is also reported.

Below is a typical nightmare of one of our patients:

I was in a tunnel knee-deep in mud. It was pitch black, but I could see light at the end. I felt a cold chill on my neck as if someone was breathing down my neck. I thought it was the grim reaper, I knew I had to get to the light.

There may be several reasons for these experiences (**Box 8.2**). There is a common belief that, when on ICU, it is better that a patient does not remember anything. However, it is increasingly realised that false memories or delusions during an ICU stay can have a significant impact on psychological recovery after ICU[22] whereas factual memories of ICU may reduce anxiety.[23]

Box 8.2 Psychological problems

Illness
Sedation technique
Withdrawal
No communication aids
Lack of clear night/day
Continuous noise of alarms
Sleep disturbance – lack of rapid-eye-movement sleep

It now seems likely that delusional memories of ICU and nightmares are associated with post-traumatic stress disorder (PTSD). PTSD is a normal reaction to severe stress and is similar to a grief reaction to bereavement. It occurs in about 1% of the population and increases to 10% in victims of road traffic accidents and 65% in prisoners of war. About 15% of patients have the typical disorder post-ICU. In those with adult respiratory distress syndrome, the incidence increases to 27.5%.

PTSD is the development of characteristic symptoms after being subjected to a traumatic event. PTSD can be triggered by any memory or mention of something to do with the traumatic event and is characterised by intrusive recollections, avoidance behaviour and hyperarousal symptoms.[24]

There is no doubt that a graded exercise programme is of benefit to aid physical recovery in such ICU patients.[14] Drugs such as fluoxetime (Prozac) do not seem to benefit such patients, even though there is a great temptation to use antidepressants in these patients.[25]

Various strategies to deal with the psychological sequelae of ICU stay have been tried.

- *During ICU stay:* There is no doubt that continuous intravenous sedation has been identified as an independent predictor of a longer duration of mechanical ventilation, ICU stay and total hospital stay.[26] Kreiss et al[27] demonstrated that, in 128 adults, ICU stay was reduced from an average of 7.3 to 4.9 days by the daily interruption of the sedative regimen. This regimen may have had an impact by reducing PTSD as the patients are more likely to have some recollection of their ICU stay, thus helping them to understand the reasons for the need for their prolonged rehabilitation period. However, a recent article[28] demonstrated no difference in length of stay with protocolised sedation with or without daily interruption of sedation. Concerns have been raised as to the type of sedative agent used in ICU. It is well known that etomidate may cause an excess in mortality in trauma patients in ICU[29] and propofol may do the same in head-injured patients at doses greater than 5 mg/kg per hour.[30] The decision to use benzodiazepines such as midazolam increasingly may be associated with dependence. This has been studied; 21 out of 148 ICU patients were discharged home on oral benzodiazepine, of whom 10 were still taking them at 6 months post-discharge having not been on them pre-ICU.[31] Lorazepam has been promoted as the benzodiazepine of choice for sedation in ICU[32] and was preferred by a task force in the USA for adult patients in ICU.[33] More recently, however, Panharipande et al have found a dose-dependent increase in delirium with the use of lorazepam.[34]

  The whole concept of delirium in patients including those who are critically ill has now been reviewed and monitoring and management of delirium is now published as a NICE guidance document.[35]
- *When building or modifying ICUs:* remember that windows and 24-hour clocks visible to patients may help re-establish circadian rhythms and the use of curtains to ensure patient dignity should not be forgotten. There has been some interest in appropriate colours that should be used in ICU décor, avoiding colours that cause alarm in the animal kingdom, such as red, yellow and black.

POST-ICU DISCHARGE

Visiting patients on the ward post ICU discharge and giving them an information booklet helps to prepare them better for the long rehabilitation process ahead.

As well as three ICU follow-up clinic appointments in the year after their discharge, patients with PTSD are encouraged to visit the ICU and, with the help of a diary, reconstruct the lost period of time in the patient's life. We are considering the use of photos of patients whilst they are on ICU to help them understand how ill they actually were.

CONCLUSION

It is important to assess patient satisfaction or dissatisfaction with their follow-up. This may be audited by questionnaire during their third visit to the follow-up clinic at 1-year post ICU discharge.[36]

In the UK, follow-up clinics were recommended by the Audit Commission in 1999 (Criticial to Success)[2] and in the Comprehensive Critical Care document in 2000,[3] yet only a small number of hospitals have been able to fund such a service. Griffiths et al[37] demonstrated that clinics are not widely established and show marked heterogeneity. Of those established, only two-thirds are funded and most do not have a prenegotiated access to other outpatient services. The PRaCTICaL study is, to date, the only evaluation of follow-up clinics that were nurse-led and did not demonstrate a cost–benefit analysis.[38] A similar study measuring the impact of a multidisciplinary clinic might come up with a different conclusion. The NICE 083 Guideline[39] has now been around for 3 years and has yet to be widely implemented. It requires a rehabilitation coordinator. Effective follow-up of patients after their critical illness may

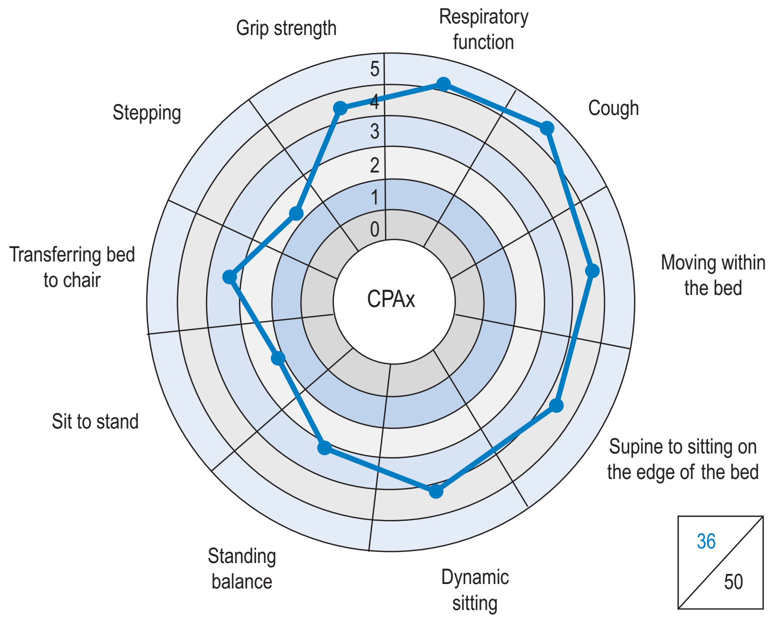

Figure 8.7 This radar chart is plotted to represent a patient's CPAx score. The image demonstrates that his respiratory function, cough and bed mobility are strong, but we can clearly see that his rehabilitation should be tailored to work on gait re-education, transferring from bed to chair and sit to stand. *(From Chelsea and Westminster NHS Foundation Trust (01/03/2010), with permission.)*

well be a future quality indicator of a hospital's critical care service. Meanwhile there is a massive increase in literature related to outcome following critical illness as health economists and intensivists try to make some sense out of the cost-effectiveness of intensive care.[40–43] Further studies are under way. The DiPEx study seeks to obtain a variety of patient and relative experiences of critical care (www.dipex.org). I-CANUK is a website that is being set up to provide a forum and voice for those involved in patient care following intensive care discharge and to support research into potential therapies following critical illness.

There have been few validated tools for the assessment of intensive-care-associated weakness, but recently the Chelsea Critical Care Physical Assessment tool (CPAx) has been developed.[44] The CPAx is a numerical and pictorial scoring system, based on a composite of ten commonly assessed components of physical function, as well as grip strength, measured as a percentage of those predicted for age and gender (**Table 8.2** and **Fig. 8.7**). Each component is graded on a six-point Guttman scale from complete dependence to independence, giving an overall score out of 50. The CPAx is completed daily by the physiotherapist and the score is plotted on a radar chart at the patient's bedside. Progress can be monitored as a daily trend, which lends itself well to the fluctuating status of the critically ill patient.

Preliminary work suggests that the CPAx is a valid measure that can be administered consistently between therapists. In an ongoing project, unpublished data of 314 patients also suggest predictive validity for hospital discharge location. Empirically, it appears to be a useful tool for motivating patients in rehabilitation and for communication with patients and relatives. It is hopeful that following full evaluation of the CPAx, it could be implemented as a universal method for monitoring progress during and after critical illness. Further results of this project will be published in 2013.

Lastly, much work needs to be done to provide an evidence base for the impact of critical care on carers and relatives. The King's College London and the King's Fund have tested the use of patient experience interviews using experience-based co-design (EBCD).[45] In EBCD, trained interviewers interview local patients and staff over several months, and then use edited films of the patient interviews to stimulate work between patients and staff to redesign services.

In a recent modification of the EBCD known as AEBCD (accelerated experience-based co-design) edited films are being produced not from local interviews but from an existing archive of patient interviews held by the University of Oxford, potentially saving several months of work and staff time. Films of patients talking about their experiences of two different conditions (intensive care and lung cancer) are being used in close partnership with patients, relatives and staff in two different hospital trusts (Royal Brompton and Harefield and Royal Berkshire) to help them together plan and implement improvements in care. The approach is being tested in a National Institute for Health Research study (HS&DR 10/1009/14); results of this project should be available in 2013.[46]

Table 8.2 The Chelsea Critical Care Physical Assessment tool (CPAx)

ASPECT OF PHYSICALITY	LEVEL 0	LEVEL 1	LEVEL 2	LEVEL 3	LEVEL 4	LEVEL 5
Respiratory function	Complete ventilator dependence Mandatory breaths only May be fully sedated/ paralysed	Ventilator dependence Mandatory breaths with some spontaneous effort	Spontaneously breathing with continuous invasive or non-invasive ventilatory support	Spontaneously breathing with intermittent invasive or non-invasive ventilatory support Or continuous high-flow oxygen (>15 L)	Receiving standard oxygen therapy (<15 L)	Self-ventilating with no oxygen therapy
Cough	Absent cough, may be fully sedated or paralysed	Cough stimulated on deep suctioning only	Weak ineffective voluntary cough, unable to clear independently (e.g. requires deep suction)	Weak, partially effective voluntary cough, sometimes able to clear secretions (e.g. requires yanker suctioning)	Effective cough, clearing secretions with airways clearance techniques	Consistent effective voluntary cough, clearing secretions independently
Moving within the bed (e.g. rolling)	Unable, maybe fully sedated/paralysed	Initiates movement Requires assistance ≥2 people (maximal)	Initiates movement Requires assistance ≥1 person (moderate)	Initiates movement Requires assistance 1 person (minimal)	Independent in ≥3 seconds	Independent in <3 seconds
Supine to sitting on the edge of the bed	Unable/unstable	Initiates movement. Requires assistance ≥2 people (maximal)	Initiates movement. Requires assistance ≥1 person (moderate)	Initiates movement. Requires assistance 1 person (minimal)	Independent in ≥3 seconds	Independent in <3 seconds
Dynamic sitting (i.e. when sitting on the edge of the bed/ unsupported sitting)	Unable/unstable	Requires assistance ≥2 people (maximal)	Requires assistance ≥1 person (moderate)	Requires assistance 1 person (minimal)	Independent with some dynamic sitting balance (i.e. able to alter trunk position within base of support)	Independent with full dynamic sitting balance (i.e. able to reach out of base of support)
Standing balance	Unable/unstable/ bedbound	Tilt table or similar	Standing hoist or similar	Dependent on frame, crutches or similar	Independent without aides	Independent without aids and full dynamic standing balance (i.e. able to reach out of base of support)
Sit to stand (starting position: ≤90° hip flexion)	Unable/unstable	Sit to stand with maximal assistance (e.g. standing hoist or similar)	Sit to stand with moderate assistance (e.g. 1–2 people)	Sit to stand with minimal assistance (e.g. 1 person)	Sit to stand independently pushing through arms of the chair	Sit to stand independently without upper limb involvement
Transferring from bed to chair	Unable/unstable	Full hoist	Standing hoist or similar	Pivot transfer (no stepping) with mobility aid or physical assistance	Stand and step transfer with mobility aid *or* physical assistance	Independent transfer without equipment
Stepping	Unable/unstable	Using a standing hoist, or similar	Using mobility aids *and* assistance >1 person (moderate)	Using mobility aid *and* assistance 1 person (minimal)	Using mobility aid *or* assistance 1 person (minimal)	Independent without aid
Grip strength (predicted mean for age and gender on the strongest hand)	Unable to assess	<20%	<40%	<60%	<80%	≥80%

Clinical information systems

David Fraenkel

Clinical record keeping requires an integrated system to manage the information, including its acquisition during clinical care, and archiving and availability for future clinical, business and research uses.

The term 'clinical information systems' (CIS) refers to computerised systems for managing the clinical record, often within specialised areas of a hospital, such as intensive care, emergency medicine, operating theatres or cardiology. CIS for intensive care units (ICUs) have been developing since the late 1980s; however, their implementation has been limited by cost, functionality and clinician acceptance.[1–9]

The electronic medical record (EMR) and electronic health care records (EHR) embrace respective hospital and community-wide electronic systems for managing patient records, which may be integrated with the more specialised CIS. Over the next decade we can expect to see EHR implementation throughout the health systems of the more developed nations. The driving incentive is community concern for safety and quality in health care and the EHR is the single most powerful measure to produce a safer, more effective and efficient health care system.[1,2,9]

In 2002 the National Health Service (NHS) in the UK embarked on an ambitious National Programme for Information Technology (NPfIT) featuring a national summary care record (SCR) or 'spine' to hold limited essential information on each consenting patient. Additional features included picture archiving and communication systems (PACS), more detailed data held on integrated local computer systems, electronic prescribing and computerised physician order entry (CPOE).[4] NPfIT was described as the largest ever IT project and organisational change in the largest global organisation. Not surprisingly it has encountered major difficulties and deficiencies, with some suggesting it was the largest ever civil IT project disaster, leading towards a more localised and modest set of objectives.[5]

The US government has placed a high priority on electronic health records.[1,2,9] The US implementation rate of EMR and CIS is one of the highest in the world as a result of these quality, governance and financial incentives. However, as would be expected from the heterogeneous nature of the health care system, the capacity for transferring patient records and data sharing is restricted by the lack of common standards.[8,9] Some of the European nations have the most complete roll-out of EMR and CIS, although variations in systems and standards also produce similar challenges.

In Australia, the HealthConnect strategy has been largely focused on broadband connections for primary health care providers and establishing data dictionaries and standards, with limited strategies or funding for actual implementation of EHRs. Efforts to establish EHRs and EMRs have been hindered by the difficulties of establishing a national unique patient identifier. Meanwhile there has been a slow increase in ICU-CIS with some attempts at a regional approach.

The current best examples of effective national strategies are provided by Canada and New Zealand. They have worked to establish common minimal standards, rather than being overly inclusive, and required vendors to comply. Implementation has been focused on incremental and iterative change on a more regional basis, with smaller projects and clinical inclusiveness.

FUNCTIONS AND ADVANTAGES OF CIS

CIS seek to deliver several key benefits (**Box 9.1**).[1] These include the automation of repetitive manual tasks, improved accuracy through reductions in human error, attributable records simultaneously available from multiple points of care and integration with other bedside equipment and information systems. The built-in error checking and knowledge-based systems should also provide a safer and higher-quality clinical process. The CIS electronically capture the data and make this information potentially available to a multitude of systems. This obviates the need for repetitive manual data entry or transcription, while making the data accessible for a range of purposes that may include clinical, business and research reporting.

The ICU is already a technology-rich environment, where bedside devices process and provide data elements in electronic format. Similarly, many clinical measurements are available on monitors, ventilators and pumps. Traditionally, these electronically derived values are transcribed onto observation charts and paper-based clinical records, as are repetitive clinical observations and arithmetic calculations, which are often performed manually or with the aid of a

Box 9.1 Clinical information systems (CIS) benefits

1. Recording of bedside observations
   a. Automation of physiological data collection
   b. Reduction in transcription and arithmetic errors
   c. Downloading from bedside therapeutic devices (e.g. pumps, ventilators)
2. Clinical documentation
   a. Legible and attributable clinical record
   b. Structures and cues encourage comprehensive documentation
   c. Electronic record of drug prescription and administration
   d. Attributable record simultaneously available from multiple points of care
3. Access to additional clinical information at the bedside
   a. Pathology results
   b. Digitised medical imaging and reports
   c. Digital clinical photographs
   d. Other hospital systems (e.g. admission/discharge/transfer (ADT), CIS)
4. Bedside decision support systems
   a. Passive
      (i) Improved and accessible clinical record
      (ii) Online clinical policies and procedures
      (iii) Online knowledge bases
      (iv) Online literature searches
   b. Active
      (i) Investigative and therapeutic management algorithms
      (ii) Clinical pathways
      (iii) Drug allergy and interaction alerts
      (iv) Drug dosing and monitoring support
      (v) Antibiotic selection and prescribing
      (vi) Ventilation and haemodynamic management systems
5. Medicolegal archiving
   a. Audit trail for all changes during episode of care
   b. No ability to change once archived
   c. Secure long-term storage and ensured availability
6. Clinical database
   a. Long-term accessible storage of relevant clinical data
   b. Industry-standard database format
   c. Efficient and flexible query and reporting solutions
   d. Scheduled and ad hoc reports
   e. Clinical, research and management requirements

calculator. The voluminous observation charts present a challenge for both storage and access, and transcription errors and arithmetic errors are prolific in these paper systems.

The CIS automates the process of electronic data collection from monitors, ventilators, infusion pumps, dialysis/filtration equipment, cardiac assist devices and other bedside devices and provides a real-time spreadsheet with arithmetic accuracy. Incorporation of clinical documentation and progress notes provides a legible and attributable record of events.

The patient record can then be accessed from geographically distant workstations in the ICU, the hospital, and even from other more remote sites. As long as the system is running, the record is easy to locate and always available.

A major contribution of CIS to clinical safety and quality is through the provision of an electronic prescribing and administration record for drugs and fluids. Errors in prescription and administration are a leading cause of adverse events with associated morbidity.[1,2] CIS ensure legibility, attribution and completeness of administration and prescribing. However, more active forms of decision support such as dose modification for organ failure, preventing prescription in allergy and identifying important drug–drug interactions are not standardised and require further development.[6–9]

ARCHITECTURE AND COMPONENTS OF CIS

BASIC CIS ARCHITECTURE

All CIS share certain basic components consisting of workstations, a network and central servers (**Fig. 9.1**). The user interface is presented at the workstation, which is usually at each bedside but may also be in nearby central and administrative areas, such as the nurses' station, or more distant in the offices of clinical or administrative staff. Workstations commonly consist of relatively standard personal computer (PC) hardware being desk, pendant or trolley mounted, but may include laptops or personal digital assistants (PDAs) with wireless systems where technical challenges related to speed and reliability of data transmission can be overcome.

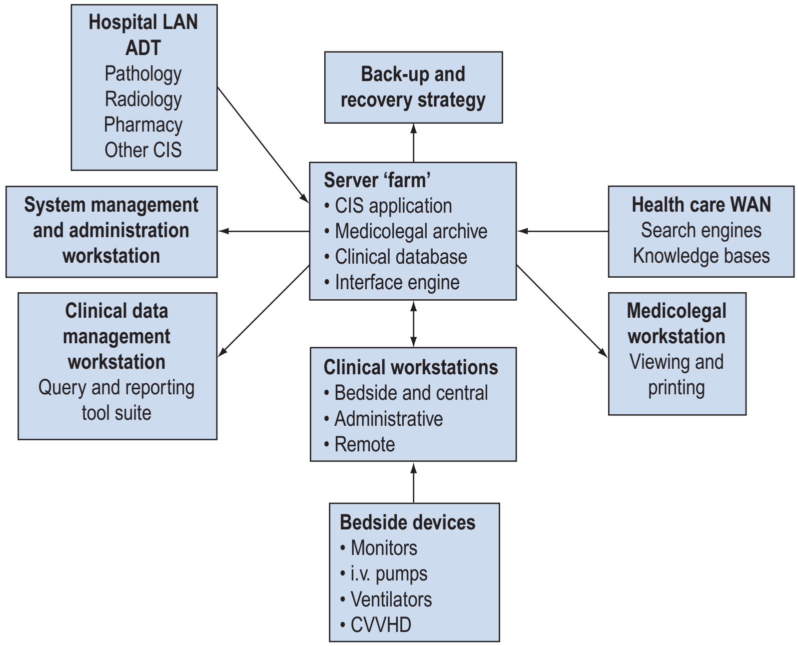
Most CIS allow other applications, such as PACS, word processing or email, to be run on the same PC, but this is potentially a rich source of system conflicts and requires careful administration.

Workstations are linked to each other and a centralised set of servers through a network of communication cables. Hubs, switches and routers control network traffic. A dedicated network, either actual or virtual, enhances system performance, but it is important to ensure built-in redundancy in network loops and power sources to minimise potential interruptions from physical disruption or component failure.

The configuration of computer servers varies widely and the best solutions may depend upon organisational IT architecture. Locally installed servers are becoming less common, whereas centralised and physically remote servers still offer technical challenges but some advantages in support.

CIS usually require a separate workstation or server to manage the interfaces with other systems. These include hospital demographics (ADT systems for admission/discharge/transfer), pathology laboratory, pharmacy, radiology and hospital finance. Interfacing requires a software platform known as an interface

Figure 9.1 Clinical information systems (CIS) architecture. LAN, local area network; WAN, wide area network; ADT, admission/discharge/transfer; CVVHD, continuous venovenous haemodialysis.



engine. Additional software identifies the relevant data and directs and processes these data to the correct field in the appropriate format. Due to the huge variety of current and legacy systems, this process almost always requires custom-written code and programming, representing one of the major risks and expenses of systems integration.[4,5]

Bedside monitoring systems usually include a central station or server that can be linked with the CIS servers to transfer their downloaded information back to the bedside. Transferring data from other bedside devices is usually achieved by a cable connection from the device to a bedside concentrator in the patient bay. The connection requires an electronic decoder, which is specific to the manufacturer and model of the device. The decoder must then communicate with the central servers via a subsidiary server that provides the software translator to complete the interface. A selection of established interfaces to commonly utilised equipment exists, but often additional customised interfaces must be written.

MEDICOLEGAL STORAGE

Electronic data capture does not necessarily result in long-term electronic data storage. Many CIS sites have continued to require the printing out of all reports from the patient episode to store in the paper-based hospital medical record, although this is increasingly because of local politicolegal requirements rather than technical limitations. Modern servers have extensive and expandable storage capacity, albeit this can be rapidly consumed by the equally enormous amount of data being collected from every patient. When the choice of storage solution is made, it is equally important to be aware that the format of data storage is determined by the anticipated use of the data and to ensure that future software upgrades do not render the stored data unreadable.

Data archiving for medicolegal purposes requires that the clinical information be readily accessible and preferably presented in exactly the same format as it was recorded and reviewed by the clinicians during the episode of patient care. Any changes to the clinical record during the patient episode must be clearly displayed and attributable – this is known as an audit trail or change history. An audit trail is a standard feature of most CIS and actually offers improved accountability over paper-based systems. It may be desirable to make it impossible to alter the record after the patient episode, which requires specialised storage formats or strict access restrictions to the data archive.

Once the record is stored, by whatever method, it must be protected from accidental loss. This usually requires a carefully engineered and documented management plan with regular scheduled back-ups, off-site storage of duplicates and robust recovery strategies. When these requirements are fulfilled, the electronic medicolegal archive can readily exceed the performance of a paper-based record through its assured availability and authenticity.

CLINICAL DATABASE STORAGE

A major objective of CIS is to provide a comprehensive clinical database that will accumulate data in real time

Box 9.2 Clinical information systems (CIS) implementation

1. Professional project management
   a. Structured multidisciplinary team
      (i) Sponsor, director, manager, representatives
      (ii) Medical, nursing, allied health, managerial

   b. Unresolved issues
   c. Process improvement
6. System management plan
   a. Identification of system components
   b. Departmental and individual roles and responsibilities
   c. Identification of vendor responsibilities
   d. Back-up schedules and recovery plans
7. Support contracts
   a. Scope and level of support
   b. Pricing
8. Future issues
   a. Ongoing management of 'special projects'
   b. Continued development and innovation
   c. System upgrades
   d. Scheduled hardware replacement
   e. System obsolescence and replacement

that can be stored and queried for a wide range of reports for a variety of purposes. The relevant data need to be held in an accessible and readily searchable database that will allow a variety of sophisticated reports to be prepared on both a scheduled and an ad hoc basis. These requirements are quite different from those of medicolegal storage and usually require a separate form of data storage, commonly known as a clinical database, data repository, data warehouse or data management solution.

There may be a requirement to adopt a significantly different database structure from the core CIS database, which may have been designed with prospective user configurability in mind, rather than allowing easy location of data fields in a structure designed for rapidly processing queries. The design of the clinical database is a compromise between saving effectively the large amount of data collected while maintaining speed and ease of use in running queries. Even when the vendor has utilised an industry-standard database application, such as Oracle or SQL, in the core CIS application designing and running queries may still present a challenging specialist task because of the complexity of the table structure or the huge amount of aggregated data.

The clinical data management solutions currently offered are quite diverse. One solution simply provides an industry-standard data transfer protocol (e.g. 'ODBC driver') as a means of accessing the data. The local circumstances of each hospital then dictate customised queries or secondary database designs for local use. Alternatively, an industry-standard query tool is used to generate reports from the core CIS database, but the number of queries that can be designed and preconfigured in this fashion is often limited, particularly as the user configurations of the CIS vary widely. There is inevitably a compromise between standardisation and flexibility. Data fields must be standardised in the configuration of the CIS to allow standard queries to be performed. Some CIS solutions offer a proprietary subsidiary database containing selected clinical data with a wider range of reports preconfigured into the query tool.

EVALUATION AND IMPLEMENTATION OF CIS

Clinicians always underestimate the managerial requirements, human resource demands and opportunity costs of CIS implementation.[1–5] The process should be viewed as a major project requiring advanced planning and management skills (**Box 9.2**). A single site project may take 1–2 years, and a multisite or regional project 2–5 years. The project team must be multidisciplinary, consult widely and consider workplace flows and processes, or else a suboptimal result is guaranteed.[4–8] The CIS will impact on medical, nursing, allied health, managerial and technical staff within the ICU, together with those from other clinical disciplines. Involvement of hospital information management staff is essential. Extensive documentation and continued scheduled reviews are required throughout the process.

Business case development to secure funding is always problematic and may be assisted by the quality benefits of CIS implementation.[3] The most basic system can be expected to cost in the order of AUD $25 000–50 000 per bed, while more advanced systems may be two to three times that cost. Annual recurrent costs are significant and usually exceed 20% of the capital cost of the system.

The CIS industry is subject to the same vagaries as other parts of the IT industry, including high turnover of personnel and frequent inability to deliver on promised functionality and timelines. CIS selection is best conducted as a formal tender process, and the

Box 9.3 Clinical information systems (CIS) evaluation

1. Vendor characteristics
   a. Monitoring of software experience
   b. Niche specialty products, cf. health care-wide
   c. Development base by specialty and geography
2. Preliminary evaluation
   a. Evaluate tender documents
   b. Product demonstration
   c. Prepared and impromptu scenario testing of product
   d. Ensure all required components identified, e.g. database, interfaces, etc.
   e. Comparative levels of best fit for needs and specifications
3. Site visits to installed customer base
   a. Reference sites and 'sites like us'
   b. Demonstrations with vendor
   c. Candid visits without vendor
   d. Observe functionality
   e. Examine interfaces
   f. Explore support issues
4. Interfaces
   a. Identify requirements
   b. Assess vendor capabilities
   c. Inspect working interfaces
   d. Customisation scope and cost
5. Technical issues
   a. Industry-standard hardware and software
   b. Local acceptability
   c. Integration with existing systems
   d. Upgrade paths
   e. Network specifications
   f. Network costs and management
6. Support issues
   a. Location and availability
   b. Product support specialists
   c. Technical engineers
   d. Level of risk sharing
   e. Whole-of-life costing

evaluation of submissions is a complex task (**Box 9.3**). Availability and expense of on-site support during and following implementation are also critical factors.

Implementation planning should be detailed and requires a full-time project officer on site. A standard implementation for a single site needs 4–6 months prior to the 'go live' date with hospital-wide consultation, issue management and carefully scheduled staff training. Multisite and regional implementations may shorten individual implementation times, but require sophisticated management that still allows for site-specific issues. It is desirable to have as many as possible of the interfaces and bedside devices linked to the CIS at the implementation date. This will maximise perceived benefits early and thereby encourage acceptance of the system. It should be implemented through the whole ICU as partial implementations are rarely successful.

Post-implementation review is essential to progress outstanding issues, which are usually prolific, and help establish the arrangements for the support and continued development of the system. A system management plan identifies the responsibility centres for management of the CIS components and clarifies requirements and expectations. A permanent on-site system management position is required for system maintenance, progressing outstanding issues and managing future upgrades and developments.

BENEFITS OF CIS: THE STATE OF THE ART

Basic CIS requirements are fulfilled by the majority of systems currently available:

- Charting, including tabulation of bedside observations and measurements such as fluid balance – the flow sheets are usually more than adequately flexible and configurable to meet local requirements.
- Bedside device interfaces – new devices may not have the necessary decoders and software. The expense of developing new interfaces can be considerable when calculated on a per-bed basis.
- Clinical progress notes – these are adequate but the free text may not be 'searchable', and structured text may be only marginally better.
- Keyboard skills are increasingly widespread, but may still be an issue with some clinicians.
- Drug and fluid prescription and administration are good, but not always incorporated in some systems, necessitating a separate system.

Decision support systems have previously been disappointing but their further development offers substantial benefits.[3,6–9] A legible and available record of previous and ongoing care does offer an improved level of decision support, albeit one that the general community would already expect and see as mandatory. Passive decision support with access to knowledge-based systems through CIS and hospital intranets, as well as resources such as pharmacopoeia, literature search engines and online texts and journals, is widely available. It is intuitive that these resources would improve the quality of clinical outcomes; but there is little evidence to support this.

Active decision support has not been generally available, including the flagging of drug allergies and interactions and the integration of relevant information, such as baseline renal function, recent urine output, last-measured creatinine and required dose of aminoglycoside.[3,6–9] Decision support systems to recommend antimicrobial prescribing, ventilatory therapy or haemodynamic measurement have been developed in dedicated centres of excellence, but are also not generally available, nor are they necessarily able to be migrated successfully across boundaries of international practice. The provision of prompts has been shown to be effective for routine prophylaxis and

care processes, supported by clinical pathways and guidelines.

Computerised physician order entry (CPOE) is exemplified in electronic prescribing, but its benefits extend to other areas such as pathology and radiology orders and results viewing. There is good evidence that a reduction in ordering occurs through reduced duplication and timeliness and access to results. The availability of CPOE varies with the level of systems integration and compatibility with other legacy and proprietary computer systems.[3,4,6–9] Standardised communications protocols (e.g. HL-7) are helpful but provide only similarities of electronic language. High-level interfaces require continued maintenance and development and therefore expenditure. Clinical databases remain a significant challenge, whether at a local departmental, hospital, regional or national level. Although many products are purported to include data management and query solutions, those that are available 'off the shelf' may be quite rudimentary and their development may require additional expenditure and a major commitment from the clinical staff. Part of the problem is the need for clinicians to define prospectively what is expected of the system. This requires exhaustive definition of the questions that the system should be able to answer and therefore also specification of the detailed nature of the data and queries that will be required.

Accurate analysis of diagnoses and procedures requires that key information is entered correctly and consistently and that reliable and high-quality data capture is achieved. Data entry should be 'once-only', simple and robust, and should be easily performed as the clinical scenario unfolds. There is very limited agreement and standardisation between clinicians with respect to mandatory data fields, diagnostic criteria and classifications. Standardised reports are therefore difficult to develop in different clinical environments, let alone regions or countries. The eventual adoption of common international standards and classifications (e.g. SNOMED for diagnoses, National Library of Medicines for pharmaceuticals) would greatly facilitate solution design and querying.[4] Other issues, including the speed of data access in huge data repositories, the development of unique patient/episode identifiers and privacy considerations, are still significant.[4–9]

FUTURE DEVELOPMENTS

Over the next decade CIS and the EHR should provide the most significant and comprehensive improvement in the delivery of health care in developed nations. It is difficult to justify continuing with archaic methods of record keeping, which are no longer adequate in almost all other professional, commercial, regulatory and day-to-day activities. Although financial obstacles may seem significant, the human resources and project management required for successful CIS planning and implementation are the most difficult to achieve. Clinical involvement throughout is mandatory. Prospective and cohesive clinician agreement on the identity and method of capture of data elements, together with configuration and reporting requirements, is essential. CIS implementation is not merely a technical process. Changes in work processes and cultural practices will be required, and offer some of the greatest challenges and opportunities to achieve the expected benefits.

Clinical trials in critical care

Simon Finfer and Anthony Delaney

Evidence based medicine is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients. The practice of evidence based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research.[1]

The most reliable evidence, and thus the best evidence for guiding clinical practice will generally come from adequately powered and properly conducted randomised clinical trials (RCTs). It is commonly the case, however, that there are no individual RCTs that adequately address a particular question, and so clinicians may have to assess the ability of other studies such as cohort studies, case–control studies and systematic reviews to supplement their clinical expertise. It is important that clinicians are familiar with the underlying principles and potential sources of bias in each of these study designs, so that they can incorporate evidence from reliable trials into their clinical practice and treat with appropriate caution those studies whose design makes it likely that they will produce unreliable results.

RANDOMISED CLINICAL TRIALS

The result of any clinical trial may be due to three factors: a true treatment effect, the effects of bias or confounding, or the play of chance. Randomised clinical trials, when properly designed, conducted and analysed, offer the optimal conditions to minimise bias and confounding, and to define the role that chance may have played in the results. As such, they represent the best study design to delineate true treatment effects under most circumstances. However, it is imperative that RCTs are designed, conducted, analysed and reported correctly. Studies that have not adhered to the principles outlined below may produce results that do not reflect a true estimate of treatment effects.

THE QUESTION TO BE ADDRESSED

Every trial should seek to answer a focused clinical question that can be clearly articulated at the outset. For example, 'we sought to assess the influence of different volume replacement fluids on outcomes of intensive care patients', is better expressed as the focused clinical question; 'we sought to address the hypothesis that when 4% albumin is compared with 0.9% sodium chloride (normal saline) for intravascular fluid resuscitation in adult patients in the ICU, there is no difference in the rate of death from any cause at 28 days'.[2] The focused clinical question defines the interventions to be compared, the population to be studied and the primary outcome to be considered. This approach can be formalised using the PICO system: PICO stands for Patient, Intervention, Comparison, and Outcome. In the example above:

- Patient=adult ICU patient
- Intervention=albumin
- Comparison=saline
- Outcome=28-day all-cause mortality.

The question that a trial is designed to address will vary somewhat depending on the stage of development of the proposed treatment. After development and testing in animal models, the testing of pharmaceutical agents in humans is generally conducted in three phases. Sometimes a fourth phase is added:

1. Phase I trial: testing in healthy volunteers
2. Phase II trial: first testing in population of patients with disease to be modified, usually small trials focused on establishing safety and evidence of efficacy using surrogate outcome measures. Phase II trials provide an estimate of treatment effect and baseline outcomes which can be used to calculate the sample size for phase III trials
3. Phase III: large-scale trial in patients that has sufficient statistical power to determine the effect of the treatment on the primary outcome
4. Phase IV: post-marketing open-label trials to confirm efficacy and safety once the agent is introduced into clinical practice.

Trials may be designed to answer two quite different questions about the same treatment and the design will be quite different depending on the questions to be answered. An 'efficacy trial' seeks to determine whether a treatment will work under optimal conditions, whereas an 'effectiveness' trial seeks to determine the effects of the intervention when applied in normal clinical practice. A comparison of the features of efficacy and effectiveness trials is given in **Table 10.1** from Hébert et al.[3]

Table 10.1 Comparison of study characteristics using either an efficacy or an effectiveness approach when designing a study

STUDY CHARACTERISTICS	EFFICACY TRIAL	EFFECTIVENESS TRIAL
Research question	Will the intervention work under ideal conditions?	Will the intervention result in more good than harm under usual practice conditions?
Setting	Restricted to specialised centres	Open to all institutions
Patient selection	Selected, well-defined patients	A wide range of patients identified using broad eligibility criteria
Study design	Smaller RCT using parallel group or factorial or other approaches (crossover design)	Large multicentre RCT using parallel groups, or factorial cluster
Baseline assessment	Elaborate and detailed	Simple and clinician-friendly
Study intervention	Tightly protocolised. Optimal therapy under optimal conditions	Less tightly protocolised. Implemented in usual clinical practice
Co-interventions	Tightly controlled protocols for many aspects of care	All therapy based on local practice/ experience/minimal control
Compliance	Compliance essential	Non-compliance expected and considered in sample size/analysis
End-points	Disease-related. Related to biological effect 'Surrogate' end-points	Patient-related such as all-cause mortality or quality of life
Analysis	By treatment received	Intention to treat
Sample size	Generally <1000 and often <100 patients	Several thousand patients
DATA MANAGEMENT		
Data collection	Elaborate	Minimal and simple
Data monitoring*	Detailed and rigorous	Minimal
Study management	Significant interventions and support from research staff	Minimal support and interventions from research team

Adapted from Hébert et al.[3]
*Data monitoring refers to the review of source documents and adjudication/verification of outcomes.

POPULATION AND SAMPLE SIZE

The population to be studied will be defined by the study question. Efficacy trials may have a very narrowly defined population, with strict eligibility criteria and many exclusion criteria. Effectiveness trials are likely to have more broad inclusion criteria and few exclusion criteria. Regardless of the design, the population to be studied should be well described. This will allow readers to assess the scientific merit of the study and allows clinicians to judge whether the results of the study could apply to their patients, to assess the 'generalisability' of the results. Trials that include only a very narrowly defined population may also face difficulties in recruiting sufficient participants to reach a definitive conclusion.

How large do trials need to be to reach a definitive conclusion? In a parallel group trial, with a dichotomous outcome (for example, alive or dead), the number of patients required to answer a question depends on four factors:

1. The percentage of patients expected to have the outcome in the control group – the control group outcome rate
2. The expected change (usually reduction) that may result from the treatment being tested – the treatment effect
3. The level of probability to be accepted to indicate that the difference did not occur by chance (i.e. the probability level at which a treatment effect will be deemed to be real) – significance level or α (alpha)
4. The desired percentage chance of detecting a clinically important treatment effect if one truly exists (power).

In the past, trials addressing issues of importance in intensive care medicine were commonly too small to detect clinically important treatment effects,[4] but fortunately this is now changing.[2,5] The conduct of underpowered trials has almost certainly given rise to a significant number of false-negative results (type II errors) leading to potentially beneficial treatments being

Table 10.2 Examples of sample size calculations

CONTROL GROUP OUTCOME RATE (%)	TREATMENT GROUP OUTCOME RATE (%)	ARR	POWER (β)	TOTAL SAMPLE SIZE
50	30	20	80	206
50	30	20	90	268
30	15	15	90	348
30	20	10	90	824
30	25	5	90	3428
15	10	5	90	1914
15	12	3	90	5582
10	8	2	80	6626
10	8	2	90	8802

ARR = absolute risk reduction.
All calculations performed with STATA 8.2, assuming a two-sided $\alpha = 0.05$.

discarded. In order to avoid these errors, clinical trials have to include a surprisingly large number of participants. Examples of sample size calculations based on different baseline incidences, different treatment effects and different statistical power are given in **Table 10.2**.

RANDOMISATION AND ALLOCATION CONCEALMENT

Two components of the randomisation procedure are critically important. The first is the generation of a truly random allocation sequence; modern computer programs make this relatively straightforward. The second is the concealment of this allocation sequence from the investigators, so that the investigators and participants are unaware of the treatment allocation (group) prior to each participant entering the study.

There are a number of benefits to using a random process to determine treatment allocation. Firstly, it eliminates the possibility of bias in treatment assignment (selection bias). In order for this to be ensured, both a truly random sequence of allocation must be produced and this sequence must not be known to the investigators prior to each participant entering the trial. Secondly, it reduces the chance that the trial results are affected by confounding. It is important that, prior to the intervention in a RCT being delivered, both groups have an equal chance of developing the outcome of interest. A clinical characteristic (such as advanced age, gender or disease severity as measured by APACHE or SOFA scores) that is associated with the outcome is known as a confounding factor. Randomisation of a sufficient number of participants ensures that both known and unknown confounding factors (e.g. genetic polymorphisms) are evenly distributed between the two treatment groups. The play of chance may result in uneven distribution of known confounding factors between the groups and this is particularly likely in trials with fewer than 200 participants.[6] The third benefit of randomisation is that it allows the use of probability theory to quantify the role that chance could have played when differences are found between groups.[7] Finally, randomisation with allocation concealment facilitates blinding, another important component in the minimisation of bias in clinical trials.[8]

The generation of the allocation sequence must be truly random. There are a number of approaches to generating a truly random allocation sequence, most commonly using a computer-generated sequence of random numbers. More complicated processes where randomisation is performed in blocks, or is stratified to ensure that patients from each hospital in a multi-centred trial or those with certain baseline characteristics are equally distributed between treatment groups, can also be used. Allocation methods based upon predictable sequences, such as those based on medical record numbers or days of the week, do not constitute true randomisation and should be avoided. These methods allow researchers to predict to which group a participant will be allocated prior to them entering the trial, which introduces the possibility of selection bias.

Whatever method is used to produce a random allocation sequence, it is important that allocation concealment is maintained. Methods to ensure the concealment of allocation may be as simple as using sealed opaque envelopes,[9] or as complex as the centralised automated telephone-based or web-based systems commonly used in large multi-centred trials. In recent years web-based randomisation has become the predominant method of assigning trial participants to treatment groups. Appropriate attention to this aspect of a clinical trial is essential as trials with poor allocation concealment produce estimates of treatment effects that may be exaggerated by up to 40%.[10]

THE INTERVENTIONS

The intervention being evaluated in any clinical trial should be described in sufficient detail that clinicians could implement the therapy if they so desired, or researchers could replicate the study to confirm the results. This may be a simple task if the intervention is a single drug given once at the beginning of an illness, or may be complex if the intervention being tested is the introduction of a process of care, such as the introduction of a medical emergency team.[11] There are two additional areas with regards to the interventions delivered in clinical trials that require some thought by those conducting the trial and by clinicians evaluating the results, namely blinding and the control of concomitant interventions.

BLINDING

Blinding, also known as masking, is the practice of keeping trial participants (and, in the case of critically

ill patients, their relatives or other legal surrogate decision makers), caregivers, data collectors, those adjudicating outcomes and sometimes those analysing the data and writing the study reports, unaware of which treatment is being given to individual participants. Blinding serves to reduce bias by preventing clinicians from consciously or subconsciously treating patients differently on the basis of their treatment assignment within the trial. It prevents data collectors from introducing bias when recording parameters that require a subjective assessment (e.g. pain scores, sedation scores or the Glasgow Coma Score). Although many ICU trials cannot be blinded (e.g. trials of intensive insulin therapy cannot blind treating staff who are responsible for monitoring blood glucose and adjusting insulin infusion rates), the successful blinding of the Saline versus Albumin Fluid Evaluation trial demonstrated the possibility of blinding even large complex trials if investigators are sufficiently committed and innovative.[2] Blinded outcome assessment is also necessary when the chosen outcome measure requires a subjective judgement. In such cases the outcome measure is said to be subject to the potential for ascertainment bias. For example, a blinded outcome assessment committee should adjudicate the diagnosis of ventilator-associated pneumonia (VAP) and blinded assessors should be used when assessing functional neurological recovery using the extended Glasgow outcome scale; both the diagnosis of VAP and assessment of the Glasgow outcome scale require a degree of subjective assessment and are therefore said to be prone to ascertainment bias.

It has been traditional to describe trials as single blinded, double blinded or even triple blinded. These terms, however, can be interpreted by clinicians to mean different things, and the terminology may be confusing.[12] It is recommended that reports of RCTs include a description of who was blinded and how this was achieved, rather than a simple statement that the trial was 'single blind' or 'double blind'.[13] Blinding is an important safeguard against bias in RCTs and, although not thought to be as essential as maintenance of allocation concealment, empirical studies have shown that unblinded studies may produce results that are biased by as much as 17%.[10]

CONCOMITANT TREATMENTS

Concomitant treatments are all treatments that are administered to patients during the course of a trial other than the study treatment. With the exception of the study treatment, patients assigned to the different treatment groups should be treated equally. When one group is treated in a way that is dependent on the treatment assignment but not directly related to the treatment, there is the possibility that this third factor will influence the outcome. An example might be a trial of pulmonary artery catheters (PAC) compared with management without a PAC. If the group assigned to receive management based on the data from a PAC received an additional daily chest X-ray to confirm the position of the PAC, they could conceivably have other important complications noted earlier, such as pneumonia, pulmonary oedema or pneumothoraces, and this may affect outcome in a fashion unrelated to the data available from the PAC. Maintenance of balance in concomitant treatments is facilitated by blinding. When trials cannot be blinded, use of concomitant treatments that may alter outcome should be recorded and reported, so that the potential impact of different concomitant treatments can be assessed.

ADAPTIVE TRIAL DESIGNS

Traditional clinical trials have followed a fixed design from the start of participant recruitment until trial completion. This approach has many advantages including simplicity and transparency, which should make the trial results more compelling. In recent years, interest in the use of adaptive trial designs has increased. An adaptive trial is one in which the trial design is changed while the trial is being conducted. The change may be quite simple and easy to understand, such as changing the sample size, and in practice most trials have an adaptive design as they allow early stopping for either efficacy or futility in response to recommendations from an independent data-monitoring committee. A less well-established but equally simple adaptive design is increasing the sample size due to a lower than expected event rate; an example of this is the PROWESS-SHOCK study where a predetermined increase in the sample size occurred in response to a lower than expected mortality rate in patients with septic shock.[14] More complex adaptive designs are used in other fields of medicine such as oncology,[15] where design changes may include changing drug doses or dropping or adding trial arms or drug doses, changing the proportion of patients assigned to each arm of a trial or seamlessly moving from phase II to phase III within a single trial.[15] Although such designs have been rare in critical care research, the failure of clinical trials in areas such as industry-sponsored sepsis research may see adaptive designs becoming more accepted in future years.

OUTCOME MEASUREMENT

All clinical trials should be designed to detect a difference in a single outcome. In general there are two types of outcomes, clinically meaningful outcomes and surrogate outcomes.

A clinically meaningful outcome is a measure of how patients feel, function or survive.[16] Clinically meaningful outcomes are the most credible end-points for clinical trials that seek to change clinical practice. Phase III trials should always use clinically meaningful outcomes as the primary outcome. Examples of clinically meaningful outcomes include mortality and measures of health-related quality of life. In contrast, a surrogate

outcome is a substitute for a clinically meaningful outcome; a reasonable surrogate outcome would be expected to predict clinical benefits based upon epidemiological, therapeutic, pathophysiological or other scientific evidence.[16] Examples of surrogate end-points would include cytokine levels in sepsis trials, changes in oxygenation in ventilation trials, or blood pressure and urine output in a fluid resuscitation trial.

Unless a surrogate outcome has been validated, it is unwise to rely on changes in surrogate outcomes to guide clinical practice. For example, it seemed intuitively sensible that after myocardial infarction the suppression of ventricular premature beats (a surrogate outcome), which were known to be linked to mortality (the clinically meaningful outcome), would be beneficial; unfortunately the CAST trial found increased mortality in participants assigned to receive antiarrhythmic therapy.[17] The process for determining whether a surrogate outcome is a reliable indicator of clinically meaningful outcomes has been described.[18]

ANALYSIS

Even when trials are well designed and conducted, inappropriate statistical analyses may result in uncertain or erroneous conclusions. A detailed discussion of the statistical analysis of large-scale trials is well beyond the scope of this chapter but certain guiding principles can be articulated:

- All trials should adhere to a predetermined statistical analysis plan as otherwise the temptation to perform multiple analyses and report only those that support the preconceived ideas of the investigators may prove irresistible. A predetermined analysis plan protects the investigators from such temptation and allows readers to give appropriate weighting to the results.
- The convention of accepting a p value of <0.05 to indicate 'statistical significance' is based on assessment of a single outcome. Assessing multiple outcomes increases the likelihood of finding a p value of <0.05 purely due to the play of chance. Each trial should have a single predefined primary outcome measure. If more than one primary outcome measure is used then the p value used to indicate statistical significance should be reduced. The simplest method is to perform a Bonferoni correction, which divides 0.05 by the number of outcomes examined to determine the new level of statistical significance. Thus for two outcomes the p value must be below 0.025, and for three it must be below 0.017. The p value may also have to be reduced further if the trial employs interim analyses.

Clinicians should pay close attention to the analysis to make certain that a true intention-to-treat analysis is presented, and that any subgroup analysis is viewed with an appropriate amount of caution.

INTENTION-TO-TREAT ANALYSIS

Trials should be analysed using the 'intention-to-treat' principle. This means that all participants are analysed in the group to which they were randomised regardless of whether they received all or any of the treatment to which they were assigned. To some readers the intention-to-treat principle may appear intuitively incorrect; it is reasonable to ask why patients who did not receive the intended treatment should be included in the analysis. Use of intention-to-treat analysis prevents bias arising from the selective exclusion of patients – termed attrition bias. In an appropriately sized trial, loss of patients at random should occur equally in both groups and inclusion of those patients will not alter the result. If loss of patients is occurring as a non-random event (e.g. because of protocol violations or intolerance of the treatment in one arm of the trial) then the trial result will be different if the lost patients are excluded. Consider a trial of a 5-day course of L-NMMA for the treatment of patients with septic shock; in the trial a number of patients who receive L-NMMA die in the first 24–48 hours and are excluded from the analysis as they have received only a little of the study treatment. A trial report based on the remaining patients who completed the treatment protocol (per-protocol analysis) will not give a true estimate of the effect of using L-NMMA in clinical practice. Although this is an extreme example, once a patient is included in a trial his/her outcome should always be accounted for in the study report.

SUBGROUP ANALYSIS

Particular difficulties arise from the selection, analysis and reporting of subgroups. Subgroups should be predefined and kept to the minimum number possible. When many subgroups are examined, the likelihood of finding a subgroup where the treatment effect is different from that seen in the overall population increases. A well-known example of this was the analysis of the treatment effect of aspirin in patients with myocardial infarction in the large Second International Study of Infarct Survival (ISIS-2) trial. Overall the trial indicated that aspirin reduced the relative risk of death at 1 month by 23%. To illustrate the unreliability of subgroup analyses, the participants were divided into subgroups according to their astrological birth signs; the analysis showed that patients born under Libra or Gemini did not benefit from treatment with aspirin.[19] Although it is easy to identify this as a chance subgroup finding, this may be much harder when the choice of the subgroup appears rational and a theoretical explanation for the findings can be advanced. For example in the Gruppo Italiano per lo Studio della Streptochinasi nell'infarto miocardico (GISSI) trial, subgroup analysis suggested that fibrinolytic therapy did not reduce mortality in patients who had suffered a previous myocardial infarct.[20] Although this finding appears biologically plausible, subsequent trials have shown quite clearly

that fibrinolytic therapy is just as effective in patients with prior infarction as in those without.[21]

Separation of patients into subgroups should be on the basis of characteristics that are apparent at the time of randomisation. Selection of subgroups using features identified after randomisation risks introducing bias as the patients have already been subjected to the different study treatments and the subgroup analysis will therefore not be comparing like with like.

TESTS OF INTERACTION VERSUS WITHIN-SUBGROUP COMPARISONS

Even when subgroups are selected appropriately, many readers will be tempted to draw inappropriate conclusions from the results. As the trial will have been designed to examine the effect of the treatment on the primary outcome in the whole study population, the best assessment of the treatment effect in any subgroup will be the effect seen in the trial as a whole. When analysing a subgroup result, the investigators should seek to answer the following question: 'Is the treatment effect in the subgroup different from the treatment effect seen in the remaining participants?' This is a test of interaction or of heterogeneity. Often the investigators err and perform within-subgroup comparisons, which instead answer the question: 'What was the effect of treatment A versus treatment B in this subgroup?' Within-subgroup comparisons are more likely to lead to unreliable results. Journals such as the New England Journal of Medicine provide guidelines for the analysis and reporting of subgroup effects.[22]

REPORTING

The reporting of randomised controlled trials has been greatly improved by the work of the CONSORT (Consolidated standards of Reporting Trials) group.[13,23] The consort statement provides a framework and checklist (**Table 10.3**) that can be followed by investigators and authors to provide a standardised high-quality report.[23] An increasing number of journals require authors to follow the CONSORT recommendations when reporting the results of a randomised controlled trial. The group also recommends the publication of a structured diagram that documents the flow of patients through four stages of the trial – namely enrolment, allocation, follow-up and analysis (**Fig. 10.1**). It is likely that the use of the CONSORT statement to guide the reporting of RCTs does lead to improvements, at least in the quality of reporting of randomised controlled trials.[24]

Trials may report results using a number of values that, taken together, will give readers a full understanding of the trial results. These may include a

Table 10.3 The Consort 2010 checklist[23] of information to include when reporting a randomised trial*

SECTION/TOPIC	ITEM NO.	CHECKLIST ITEM
TIME AND ABSTRACT		
	1a	Identification as a randomised trial in the title
	1b	Structured summary of trial design, methods, results, and conclusions (for specific guidance see CONSORT for abstracts)
INTRODUCTION		
Background and objectives	2a	Scientific background and explanation of rationale
	2b	Specific objectives or hypothesis
METHODS		
Trial design	3a	Description of trial design (such as parallel, factorial) including allocation ratio
	3b	Important changes to methods after trial commencement (such as eligibility criteria), with reasons
Participants	4a	Eligibility criteria for participants
	4b	Settings and locations where the data were collected
Interventions	5	The interventions for each group were sufficient
Outcomes	6a	Completely defined pre-specified primary and secondary outcome measures, including how and when they were assessed
	6b	Any changes to trial outcomes after the trial commenced, with reasons
Sample size	7a	How sample size was determined
	7b	When applicable, explanation of any interim analyses
RANDOMISATION		
Sequence generation	8a	Method used to generate the random allocation sequence
	8b	Type of randomisation; details of any restriction (such as blocking and block size)

Table 10.3 The Consort 2010 checklist of information to include when reporting a randomised trial—cont'd

SECTION/TOPIC	ITEM NO.	CHECKLIST ITEM
Allocation concealment mechanism	9	Mechanism used to implement the random allocation sequence (such as sequentially numbered containers), describing any steps take to conceal the sequence until interventions were assigned
Implementation	10	Who generated the random allocation sequence, who enrolled participants, and who assigned participants to interventions
Blinding	11a	If done, who was blinded after assignment to interventions (for example, participants, care providers, those assessing outcomes and how)
	11b	If relevant, description of the similarity of interventions
Statistical methods	12a	Statistical methods used to compare groups for primary and secondary outcomes
	12b	Methods for additional analyses, such as subgroup analyses and adjusted analyses
RESULTS		
Participant flow (a diagram is strongly recommended)	13a	For each group, the numbers of participants who were randomly assigned, received intended treatment, and were analysed for the primary outcome
	13b	For each group, losses and exclusions after randomisation, together with reasons
Recruitment	14a	Dates defining the periods of recruitment and follow-up
	14b	Why the trial ended or was stopped
Baseline data	15	A table showing baseline demographic and clinical characteristics for each group
Numbers analysed	16	For each group, number of participants (denominator) included in each analysis and whether the analysis was by original assigned groups
Outcomes and estimation	17a	For each primary and secondary outcome, results for each group, and the estimated effect size and its precision (such as 95% confidence interval)
	17b	For binary outcomes, presentation of both absolute and relative effect sizes is recommended
Ancillary analyses	18	Results of any other analyses performed, including subgroup analyses and adjusted analyses, distinguishing pre-specified from exploratory
Harms	19	All important harms or unintended effects in each group for (specific guidance see CONSORT for harms)
DISCUSSION		
Limitations	20	Trial limitations, addressing sources of potential bias, imprecision, and, if relevant, multiplicity of analyses
Generalisability	21	Generalisability (external validity, applicability) of the trial findings
Interpretation	22	Interpretation consistent with results, balancing benefits and harms, and considering other relevant evidence
OTHER INFORMATION		
Registration	23	Registration number and name of trial registry
Protocol	24	Where the full trial protocol can be accessed, if available
Funding	25	Sources of funding and other support (such as supply of drugs), role of funders

*We strongly recommend reading this statement in conjunction with the CONSORT 2010 Explanation and Elaboration for important clarifications on all the items. If relevant, we also recommend reading CONSORT extensions for cluster randomised trials, non-inferiority and equivalence trials, non-pharmacological treatments, herbal interventions, and pragmatic trials. Additional extensions are forthcoming: for this and for up-to-date references relevant to this checklist see www.consort-statement.org.

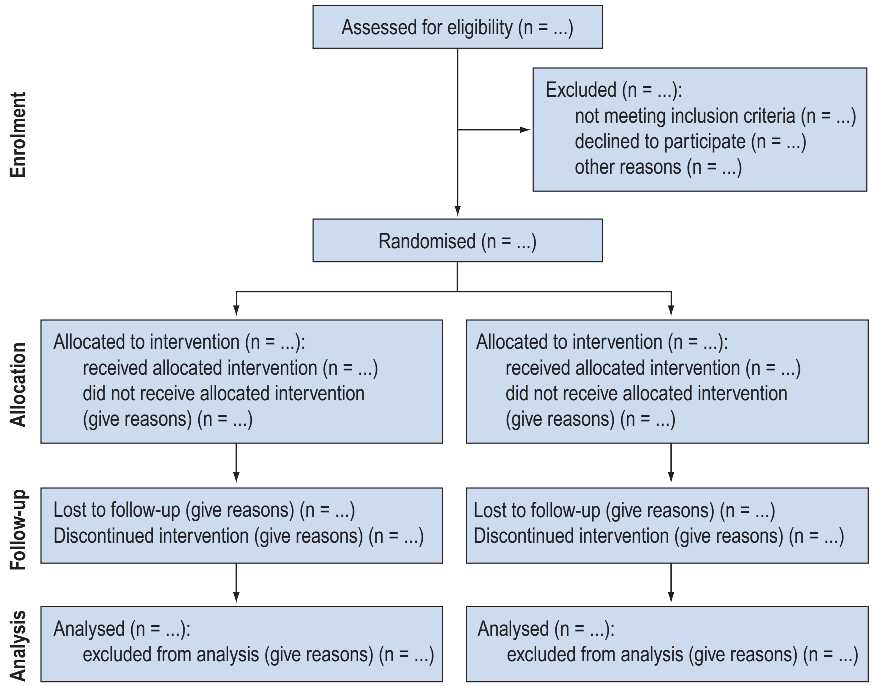

Figure 10.1 Flow diagram of the progress through the phases of a randomised trial.[23] *(From Schulz KF, Altman DG, Moher D, CONSORT Group. CONSORT 2010 statement: updated guidelines for reporting parallel group randomised trials. BMJ 2010;340:c332, with permission.)*

p value, confidence intervals and number needed to treat (or harm).

- *Probabilities:* the *p* value represents the probability that a difference has arisen by chance. In very large trials, small and clinically insignificant differences may give rise to *p* value of less than 0.05 and, conversely, a moderately sized trial may report a clinically important difference with a *p* value that is close to or greater than 0.05; *p* values should not be viewed in isolation but assessed in combination with other measures such as confidence intervals and the number needed to treat (or harm).
- *Confidence intervals:* give an indication of the precision of the result. Whenever a trial reports a difference it is reporting a difference found in a finite sample of the population of interest. If the same trial is repeated it is highly likely a slightly or very different result will be reported. If the trial is reporting a relatively small number of patients with the outcome of interest (small number of events) then the difference between the results may be large, if the trial reports a large number of events then it is likely the two results will be quite close to each other. Confidence intervals give a range of values within which it is likely the 'true' result lies – they give an indication of the precision of the result. The most commonly quoted are the 95% confidence intervals; these are the limits within which we would expect 95% of study results to lie if the study were repeated an infinite number of times, though they are often interpreted to mean that we can be 95% confident that the 'true' result lies within these limits.
- *Number needed to treat (or harm):* a useful concept for clinicians is the number needed to treat (or harm). This is the reciprocal of the absolute difference in outcomes arising from two treatments. For example in the ISIS-2 trial, patients randomised to intravenous streptokinase had an absolute reduction in mortality of 2.8%. Thus the number needed to treat to prevent one death is 100/2.8 or 35.7 patients. As the trial was very large with a large number of events (17 187 participants and 1820 deaths), this relatively small absolute reduction in mortality (2.8%) yielded a *p* value of less than 0.000001. The same calculation can be performed to calculate the number needed to harm. For example, in the CRASH trial, patients with traumatic brain injury treated with high-dose steroids had a 3.4% increase in the absolute risk of death. The number needed to harm is calculated as 100/3.4, or one extra death for every 29.4 patients treated with high-dose corticosteroids. Again, as this was a large trial (10 008 participants and 1945 deaths) the *p* value is small (p=0.00001).

ETHICAL ISSUES SPECIFIC TO CLINICAL TRIALS IN CRITICAL CARE

The ethical principles guiding the conduct of research in critical care are outlined in the International Ethical

Guidelines for Biomedical Research Involving Human Subjects,[25] in addition country-specific guidelines are provided by various national bodies. The ethical principles of integrity, respect for persons, beneficence and justice, should be considered whenever research is conducted and an appropriately convened human research ethics committee or the equivalent should assess all research to ensure adherence to these principles. As the potential participants in critical care research are particularly vulnerable, owing to the nature of the conditions and the limitations to communication that exist, special consideration needs to be given to a number of areas including informed consent.

INFORMED CONSENT

That all mentally competent participants in clinical research should give informed consent prior to entering a study is an important ethical principle. This is rarely possible for people suffering critical illness, where the disease process (e.g. traumatic brain injury, encephalitis, severe hypoxaemia) or the required treatment (e.g. intubation, use of sedative medications) may make it impossible to obtain informed consent. Even awake, alert patients may not be able to give fully informed consent when they are facing stressful and potentially life-threatening situations.[26] This applies equally to surrogate decision makers. However, the treatment of critically ill patients can be improved only through the conduct of research and in many jurisdictions this has been recognised by making special provisions for consent in emergency research including research in the critically ill. In some circumstances, it may be ethical to allow a waiver of consent for research involving treatments that must be given in a time-dependent fashion (e.g. in the setting of cardiac arrest). A waiver of consent may well improve recruitment into clinical trials; it is unclear whether this approach is universally acceptable. Another approach has been to allow delayed consent, where patients are included in the study and consent from the patient or the relevant surrogate decision maker is sought as soon as practical. Neither approach is without problems.[27]

CRITICAL APPRAISAL

Clinicians reading reports of randomised controlled trials should use a structured framework to assess the methodological quality of the trial and the adequacy of the trial report. They should also address the magnitude and precision of reported treatment effects and ask themselves whether the results of the trial can be applied to their own clinical practice. There are a number of resources available to assist clinicians in this task, notably the Users' Guides to the Medical Literature, originally published in JAMA and the Critical Appraisal Skills Program from Oxford, UK, both of which are freely available on the internet.[28,29] These resources provide a structured framework that allows any reader to perform a systematic critical appraisal of almost any piece of medical literature. A checklist is provided for the appraisal of randomised controlled trials (**Box 10.1**).

Box 10.1 Critical appraisal checklist for randomised controlled trials[28]

I. Are the results of the study valid?

Primary guides: Was the assignment of patients to treatments randomised?

1. Were all patients who entered the trial properly accounted for and attributed at its conclusion?
2. Was follow-up complete?
3. Were patients analysed in the groups to which they were randomised?

Secondary guides: Were patients, health workers, and study personnel 'blind' to treatment?

1. Were the groups similar at the start of the trial?
2. Aside from the experimental intervention, were the groups treated equally?

II. What were the results?

How large was the treatment effect?

1. How precise was the estimate of the treatment effect?

III. Will the results help me in caring for my patients?

Can the results be applied to my patient care?

1. Were all clinically important outcomes considered?
2. Are the likely treatment benefits worth the potential harms and costs?

OBSERVATIONAL STUDIES

Although RCTs are the optimal study design for deciding whether or not a treatment 'works', not all research questions can be addressed with this type of study. When the disease is rare, the outcome is rare or the treatment may be associated with harm, other study designs may be more appropriate. In these circumstances a cohort study or case–control study may be used to explore potential associations between exposure to a treatment and the occurrence of outcomes.

DESCRIPTIVE STUDIES

Case reports, case series and cross-sectional studies are all examples of descriptive studies. These types of studies may be important in the initial identification of new diseases such as HIV/AIDS[30–33] and SARS.[34] The purpose of these studies will be to describe the 'who, when, where, what and why' of the condition, and so further the understanding of the epidemiology of the disease. It is important that clear and standardised definitions of cases are used, so that clinicians and researchers can identify similar cases from the information provided. Although there are some famous examples where data from simple observational studies has been used to solve particular problems,[35] in general only very limited inferences can be drawn from descriptive data. In particular, it is dangerous to draw conclusions about 'cause and effect' using data from descriptive studies alone.[36]

ANALYTICAL OBSERVATIONAL STUDIES

There are two main types of analytical observational studies: case–control studies and cohort studies.

Case–control studies are performed by identifying patients with a particular condition (the 'cases'), and a group of people who do not have the condition (the 'controls'). The researchers then look back in time to ascertain the exposure of the members of each group to the variables of interest.[37] A case–control design may be appropriate when the disease has a long latency period and is rare. Cohort studies are performed by identifying a group of people who have been exposed to a certain risk factor and a group of people who are similar in most respects apart from their exposure to the risk factor. Both groups are then followed to ascertain whether they develop the outcome of interest. Cohort studies may be the appropriate design to determine the effects of a rare exposure, and have the advantage of being able to detect multiple outcomes that are associated with the same exposure.[38]

Both types of observational studies are prone to bias. In particular, although it is possible to correct for known confounding factors using multivariate statistical techniques, it is not possible to control for unknown or unmeasured confounding factors. There are a number of other biases that may distort the results of observational studies; these include selection bias, information bias and differential loss to follow-up.[38,39] Critical appraisal guides for observational studies are available to help readers assess the validity of these studies.[40] These limitations and inherent biases mean that observational studies may not always provide reliable evidence to guide clinical practice, although it has been argued that this is not always the case.[41,42]

SYSTEMATIC REVIEWS AND META-ANALYSIS

Systematic reviews have been proposed as a solution to the problem of the ever expanding medical literature.[43] A systematic review utilises specific methods to identify and critically appraise all the RCTs that address a particular clinical question and, if appropriate, statistically combine the results of the primary RCTs in order to arrive at an overall estimate of the effect of the treatment. By systematically assembling all RCTs that address one specific topic, methodologically sound systematic reviews can provide a valuable overview for the busy clinician. They play an important role in providing an objective appraisal of all available evidence and may reduce the possibility that treatments with moderate effects will be discarded owing to false-negative results from small or underpowered studies.[44] The use of meta-analysis could have resulted in the earlier introduction of life-saving therapies such as thrombolysis.[45] By using systematic methods, meta-analyses can provide more accurate and unbiased overviews, drawing conclusions that are often at odds with those of 'experts' and narrative reviews.[46,47]

In spite of these advantages and benefits, there are still problems with interpretation of meta-analyses. Like all clinical trials, they need to be performed with attention to methodological detail. There are guidelines for performing and reporting systematic reviews.[48,49] It is clear that in the critical care literature these guidelines are not always followed.[50] Clinicians should critically appraise the reports of all systematic reviews and meta-analyses regardless of the source of the review, using an appropriate guide.[51,52] Problems with interpretation can arise when the results of meta-analysis are at odds with the results of large RCTs that address the same issue;[53,54] this is not uncommon and clinicians will have to compare the methodological quality of the meta-analysis and the RCTs included in it with the validity of the large RCT in order to decide which provides the most reliable evidence.[55,2]

Palliative care

Sarah Cox and Neil Soni

The World Health Organisation defines palliative care as an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual (**Box 11.1**).[1]

Palliative care should be part of the care of patients identified as dying on ICU. In addition, the principles of palliative care may be appropriate for patients with life-limiting disease admitted to ICU for treatment of reversible causes such as neutropenic sepsis as a consequence of palliative chemotherapy. The palliative care team may also have a role in the care-of-patients with long-term conditions being considered for ICU admission. This chapter reviews the issues around identification and management of palliative and end-of-life care for ICU patients. It will also address the practical, ethical and emotional issues that arise.

PRE-ADMISSION TO ICU

Admission to ICU requires a judgement about the likelihood of benefit for the individual patient. Whilst this is often a discussion between the ICU or critical care outreach team, the usual medical team and the patient and family, the palliative care team may have an important role to play. Firstly, they can be part of a discussion about appropriateness of aggressive treatment. Secondly, it may be helpful to underline that if ICU care is not the chosen course of action, there is another specialist team who will be involved to ensure good symptom control and emotional support. Their expertise in communication can be useful in clarifying goals according to the patient's wishes, if known, including access to pre-existing advance care plans from community health care teams. They can support family and ward staff with alternative care plans. They may become the point of contact for the family providing continuity and reassurance in what is often an emotionally fraught situation.

PATIENTS ON ICU WHO ARE DYING

Around 5% of deaths in the UK and 20% of deaths in the USA occur on the intensive care unit.[2–4] Not all of these deaths could or should be predicted, but the proportion that follows a period of treatment withdrawal is increasing in both North America and Europe. This suggests an identifiable end-of-life phase, which could be managed with palliative care principles in mind, or as shared care with a specialist palliative care team.

There is great variability between services and cultures in identification of an end-of-life phase. Up to 90% of deaths in North American ICUs happen after decisions to limit life-sustaining treatment.[2] In northern Europe the figure is lower at around 50%, and 20% in southern Europe.[3,4] While these differences might be explained by the greater availability of ICU beds in America or less selective admission criteria, it is likely that they reflect, at least in part, cultural differences of expectations of treatment.

Scales such as APACHE III have been developed to help predict outcomes of ICU intervention,[5] but they are not sufficiently precise to be helpful in end-of-life decision making for an individual.[4] Frequently ICU admission represents a therapeutic trial with both clinicians and family sustaining hope until it is clear the trial has failed. Only then, which may be very late in the acute illness, will a transition to the goals of palliative care be considered appropriate. There may be an opportunity therefore to communicate uncertainty earlier on in the ICU stay so that active and palliative care can occur together.

What constitutes a good death depends on the views of the individual; however, there are some common themes from the literature including freedom from pain and other symptoms, and the ability to retain some degree of control, autonomy and independence.[6] For patients dying on ICU the last three are difficult to achieve. However, they suggest delivering treatment that supports patients' values and beliefs, including appropriate limitation of the use of aggressive treatments. Surveys of patients and ICU nurses suggest a clear overlap between them in the priority of avoiding prolongation of dying (**Box 11.2**).[6,7]

For relatives of patients dying on ICU, a good death requires attention to comfort, and more particularly to pain management. Families rate whole-person concerns highly, including feeling that their relative was at peace and retained dignity and self-respect.[8] Increased satisfaction of families is also related to clarity around the

Box 11.1 World Health Organization definition of palliative care[1]

- Provides relief from pain and other distressing symptoms
- Affirms life and regards dying as a normal process
- Intends neither to hasten nor postpone death
- Integrates the psychological and spiritual aspects of patient care
- Offers a support system to help patients live as actively as possible until death
- Offers a support system to help family members cope during the patient's illness and in their own bereavement
- Uses a team approach to address the needs of patients and their families, including bereavement counselling if indicated
- Will enhance quality of life, and may also positively influence the course of illness
- Is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better

Box 11.2 Patients' and ICU nurses' priorities for a good death

Patients[6]	*ICU nurses*[7]
Adequate pain and symptom management	Managing pain and other symptoms
Avoiding inappropriate prolongation of dying	Promoting earlier cessation of treatment or not initiating aggressive treatment at all
Achieving a sense of control	Knowing and following patients' wishes for end-of-life care
Relieving burden on others	Communicating effectively as a health care team
Strengthening relationship with loved ones	

processes of limiting treatment, with trials of treatment being explained and withdrawal or withholding of treatment occurring as expected.[9]

DECISION MAKING FOR PATIENTS AT THE END OF LIFE

INVOLVEMENT OF PATIENTS

In the 1990s the SUPPORT study team reported their prospective observation of over 9000 seriously ill hospitalised patients.[10] The authors identified overaggressive management, inadequate pain control and poor communication amongst a significant number of those who went on to die. There was evidence that physicians were often not aware of patients' wishes around medical care.

Patients' preferences for treatment may be accessed directly in only a small minority of cases admitted to ICU. Occasionally, a valid and applicable advance directive exists, or patients have a statement of wishes or have discussed their preferences for treatment with close family. The majority (up to 95%) of patients requiring admission to ITU will be unable to engage in discussions about treatment choices, and most will not have discussed their wishes with relatives or recorded them in writing.[11] Offering advance care planning to individuals with chronic progressive diseases is being encouraged, but as yet has only been taken up by a small minority. Ideally, in the future, advance care planning in patients with progressive medical conditions may be helpful in respecting patient wishes around ICU care.

Where patients are able to discuss options for treatment, it should be considered that they may have a variable understanding of medical interventions. In essence they tend to overestimate the likelihood of their success, with optimism on the part of the patient, and a reluctance to be pessimistic on the part of the clinicians.[12] However, discussions about treatment that include details of the likely outcome, and potential burden, can significantly reduce patient preferences for those treatments where the medical benefit is uncertain.[13]

INVOLVEMENT OF FAMILIES IN DECISION MAKING

The realisation that active treatment is no longer in the patient's best interests comes to health professionals, patients and families at different times. Partly this is due to experience and training and partly a sometimes-unrealistic belief in what ICU treatment can achieve. Managing the different expectations is challenging. Families want to be involved in decision making, especially around value-laden decisions such as withdrawal of life support,[14] but they will need to have clear explanations of their relative's condition and the purpose and limitations of treatment. Their role, and the role of the health care team, should be to advocate for the patient, making the decision that patient would have made had they been able.[15] Relatives are able to identify patient preferences with agreement of 80% or greater in situations where the impact of the physical insult is either mild or devastating.[16] However, there is a dramatic drop in agreement (down to around 60%) for more ambiguous scenarios associated with long-term physical or cognitive morbidity. In these situations,

relatives are more likely than patients to identify the clinical outcome as acceptable.

Effective, frequent and timely communication with relatives increases satisfaction with care and reduces anxiety in bereavement.[17] Insufficient time spent communicating with families results in poor understanding of the diagnosis, prognosis and plan of care and increased conflict.[18] Time spent is not, in itself, enough and far more important is the clinicians' ability to elicit and respond to families' views and concerns. Simply, families judge the quality of the discussion, at least in part, by how much time they are allowed to speak rather than encouraged to listen.[19] Although the communication skills of ICU staff may be excellent, the additional resource of the palliative care team can also be useful in these situations.

INVOLVEMENT OF OTHER HEALTH PROFESSIONALS IN DECISION MAKING

ICU nurses often feel frustrated by the medical plan especially when, in their view, conflicting or over-optimistic messages are given to patients or family members.[20] In contrast, physicians are reported to feel the burden of making decisions about limiting treatment and that 'it's a lot easier to say it than to do it'.[21]

Collaboration between these professionals has the potential to produce better-informed decisions, which can lead to greater satisfaction with care for patients, families and the professionals involved.[22,23] Not surprisingly inconsistent messages and non-collaborative inter-professional behaviours result in family dissatisfaction.[24] Shared decision making will reduce the burden of decision making on senior ICU physicians, but it still usually remains their ultimate responsibility. Three studies of collaborative decision making involving at least nurses, physicians and family have demonstrated the additional benefits of reduced length of ICU stay and lower costs with no increase in mortality.[22,23,25]

There is much published on the involvement of other professionals in end-of-life decision making. Lilly et al included a social worker and a chaplain in their model of family meetings;[22] others have suggested the importance of considering other specialists such as physiotherapists (respiratory therapists)[26] or palliative care clinicians.[27] Involvement of clinical ethicists has been demonstrated to improve satisfaction of both health care professionals and families and to reduce length of ICU stay and costs for patients who died.[28]

WITHDRAWAL OF AND WITHHOLDING TREATMENT

Patients identify the avoidance of inappropriate prolongation of dying in their definition of what a 'good death' might look like.[6] There is agreement in the USA and northern Europe that where treatment is not going to succeed it should be withheld or withdrawn.[4,29,30] However, there is wide variation in withholding and withdrawing treatment across countries.[4] Differences have also been measured in what ICU physicians believe they should do and what actually happens, with physicians identifying a significantly greater need for withholding or withdrawing treatment than their practice demonstrates.[5]

The ethical basis for withholding treatment is the same as that for withdrawal; however, the practice of withdrawal is often emotionally more difficult for all concerned. This may be a result of the more active nature of withdrawal.[29] It is also possible that some ICU treatments, when withdrawn, result in rapid decline and death with a greater requirement for symptomatic medication and this temporal association presents an uncomfortable comparison with the act of euthanasia. However, allowing inevitable death and euthanasia are ethically and, in most countries, legally distinct. It is the intention behind each decision to withhold or withdraw that is critical.

Decisions to limit treatment include discontinuing monitoring vital signs, withholding cardiopulmonary resuscitation, vasopressors, antibiotics and artificial hydration, and removal of mechanical ventilation. All decisions should be considered individually in terms of the benefit and burden to the patient and in the context of the goals of care. In the large, prospective study of end-of-life practices in European ICUs, the Ethicus study group identified wide variation in withdrawal (5–69%) and withholding (16–70%) of therapy.[5]

Decisions to remove or reduce mechanical ventilation at the end of life present particularly difficult ethical and practical issues. Differing practices of weaning ventilation from rapid to prolonged are described. Proponents of the former suggest that prolonged weaning prolongs dying and therefore unnecessary suffering.[31] Those in support of prolonged weaning argue that a rapid reduction in ventilation may be associated with more dyspnoea.[29] Extubation is practised by some ICU physicians who argue that there is discomfort associated with the endotracheal tube itself and that there is no ethical justification in leaving the tube in place once a decision has been made to discontinue life-sustaining treatment.[32,29] However, there is a significant incidence of stridor and laboured breathing in extubated patients, which suggests this approach may induce more symptoms than it relieves.[32]

There has been concern about the doses of opioids and benzodiazepines required to control dyspnoea and agitation, especially in rapid weaning or extubation, and whether in fact these medications themselves bring about the patient's death. The principle of double effect holds that the unintended consequence (death) is ethically acceptable because of the intended effect (symptom control). This is a controversial position with which some are uncomfortable. In fact the principle of double effect may not be relevant as small studies in ICU show

Box 11.3 Recommendations for managing the transition from active to palliative care on the ICU

- Inclusive and collaborative decision making
- Consistent communication with family that begins early
- Identification of trials of therapy with timed reassessment against clinical milestones
- Concurrent attention to symptom control, spiritual and psychological support of patient and family
- Clarity about withholding and withdrawing treatment
- Guidance for 'stepping-down' to general hospital wards
- Inclusion of organ donation in consideration
- Assessment of bereavement risk for onward referral if appropriate
- Support of staff

that the doses of opioids and sedatives required for symptom control are relatively modest[33,34] and in dying palliative care patients these drugs do not appear to hasten death.[35,36]

Given such variations in practice and potential for different interpretations of intentions in withdrawing or withholding life-sustaining treatment, excellent communication between the multiprofessional team and the family, and clear documentation of the intent and decision-making process leading to it are paramount (**Box 11.3**).

SYMPTOM CONTROL

Symptom assessment usually involves taking a detailed history from the patient to understand the cause and severity of the symptom. In many ICU patients at the end of life this is not possible and so physiological variables and behavioural observations are used as surrogate markers, such as heart rate and respiratory rate. The use of validated pain scales such as the Behaviour Pain Scale[37] or Pain Assessment Behaviour Scale[38] may provide more objective records of pain to direct changes in dose of symptomatic medication. Involvement of the specialist palliative care team may be useful when the situation is unclear or symptoms prove difficult to control.

Dyspnoea correlates most strongly with tachycardia and tachypnoea[39] and may be treated symptomatically with opioids with the addition of benzodiazepines to reduce anxiety if necessary. Treatments such as oxygen, corticosteroids and diuretics may be appropriate if they are contributing to symptomatic control of breathlessness. Signs of agitation, anxiety, or behavioural markers of pain that do not respond to opioids and may be caused by general distress can be treated with benzodiazepines. Specialist palliative care input may be helpful if symptoms fail to respond to usual measures.

Choice of opioid and benzodiazepine varies; it is important for units to use the particular drug they are familiar with. Morphine is cheap but should not be used in patients with moderate to severe renal impairment as accumulation can result in additional symptoms. Fentanyl or alfentanil are common alternatives in this situation. Drug doses should be titrated against symptoms and escalated in response to documented markers of distress.

SUPPORT FOR FAMILIES AND STAFF

Patients and families will need support in the form of effective communication and they may also need psychological support. This is often provided by ICU staff, particularly the nursing staff, with whom they may have spent significant time. Offers of additional psychological support should be made to patients and family members and accessed from the specialist palliative care team and from chaplaincy.

Palliative care continues as bereavement care after the patient dies. In practice most bereavement support from ICU is offered immediately after death or by external agencies. Needless to say, relatives need to be informed of the death in a sensitive manner; they also need to understand the cause of death. Identification of family members who may be at risk of complicated bereavement may be guided by features of the illness and death, features of the bereaved person such as psychological morbidity, their relationship with the deceased, and their social supports. Referral to a local bereavement service or requesting permission to call the family doctor and arrange an appointment may be appropriate.

Bereavement surveys suggest ways we could improve the impact of relatives' deaths on ICU including skilled communication during the critical illness and after death. Post-traumatic stress-related symptoms are more common among family members who felt information giving was incomplete.[40] These symptoms can translate subsequently to increased rates of anxiety and depression.

ICU staff have emotional responses to the death of their patients, which need to be addressed to avoid burnout or other negative long-term sequelae.[41,42] Support might include debriefing around deaths, a supportive environment, and access to psychosocial resources. Collaborative decision making would be expected to reduce staff stress about dying patients.

ORGAN DONATION

The topic of organ donation and the ICU is more fully discussed in Chapter 100. Involvement of the palliative care team may be helpful to provide additional emotional support to the family. There may also be an important role in managing signs of distress, especially during withdrawal of treatment in donation by cardiac death (DCD). In DCD the family may wish to be with the patient whilst treatment is withdrawn. This process is an opportunity for them to say goodbye and they

may have specific wishes around prayer or cultural rituals that should be elicited and honoured as far as possible. Provision should be made for appropriate symptomatic drugs to be with the patient during DCD to treat signs of distress, as these will be unpleasant for the family, although they may not be experienced as discomfort by the patient. In some units, the palliative care team takes over care of patients if they do not die within the timeframe for DCD, moving them to another ward or palliative care unit within the hospital.[43]

CARE PATHWAYS TO SUPPORT END-OF-LIFE CARE ON ICU

Pathways and protocols have been developed to improve the care of dying patients on the ICU.[44,45] The care of the dying pathway developed by the Marie Curie Centre in Liverpool, UK prompts appropriate assessment of symptoms, communication with family and patient if possible, psychological and spiritual support and support with practical issues such as open visiting and free car parking.[44] It acts as a reminder to consider the appropriateness of each treatment in terms of the burden and benefit and supports the nursing staff in monitoring and maintaining comfort on an ongoing basis.

STEPPING DOWN FROM ICU

Some patients are able to transfer out of ICU for their last days but this transition needs to be managed carefully to avoid additional family distress. The initial suggestion of stepping down from ICU is another opportunity to utilise the palliative care team's expertise.

This transition is both a physical and emotional one for patients and families who may feel that this step away from critical care in some way seals the fate of the patient. They will be concerned about losing the skilled staff and environment they know. Their anxiety may be compounded by the knowledge that there is not the same ratio of staff to patients outside ICU.[46] Clear information about changes in ward and treatments may help to reduce the anxiety.

A member of the palliative care team can be helpful in providing continuity around this transition. If invited to meet the patient and family before transfer, they can begin to understand the specific needs of patient and family members including symptom control, emotional and spiritual issues.

The move should take place in a planned way with the family given as much forewarning as possible. Ideally, the patient should not be transferred at night or weekends if this means there is less support available. Treatments and monitoring should not be discontinued immediately before transfer, although some changes may be necessary if the 'step-down' ward does not usually care for patients with arterial lines or intravenous opioid infusions. The palliative care team can help to advise about practicalities of continuing symptomatic medications after the move, and managing this transition seamlessly.

CONCLUSION

With advances in technology, there is likely to be an increase in trials of ICU treatment, and a corresponding increase in transition to palliative care on the ICU. How this is managed will depend on local access to specialist palliative care resources and the focus of the ICU staff. Limitation of treatment, in whatever guise, is a difficult area and constitutes a significant part of clinical practice on the ICU. It is immensely important to patients, their relatives and clinicians and deserves to be more openly discussed. Review of ICU deaths at mortality and morbidity meetings could include consideration of the quality of the patient's end-of-life care and family support to promote learning and improve care for subsequent patients.

ICU and the elderly

Richard Keays

The proportion of the population that is elderly is increasing in all developed and developing nations. Medical innovation and a belief that old age and disease can be defeated by a combination of personal choice and greater resources has led to rising, often unrealistic, expectations. Increasingly intensive care medicine is becoming a specialty largely focused on care of the elderly and the age-acquired co-morbidities of this patient group complicate their management. The consequence of this demographic shift in the critical care unit population has remained largely unstudied. This chapter seeks to bring together the current information on management of the elderly presenting to critical care.

DEFINITIONS

There is no agreed definition of 'elderly'. It has been defined by chronology, social role, physical capacity, threshold life expectancy and when 'active contribution is no longer possible'. Most commonly it is taken as the pension age – though this is an inherently fluid endpoint. In 1875 over-50s were defined as elderly whereas now it seems around the pension age of 65, although the over-80s are also becoming an 'identifiable' group. These chronological niceties are rarely relevant from a medical perspective as clinicians understand the poor correlation between chronological and physiological age. The medical literature has no common definition and uses a wide range of arbitrary values from 67 to 70, over-70s and, more recently, over-80s to describe population groups.[1]

DEMOGRAPHICS

More people are living longer and this trend has shown little sign of stopping. In the UK, 5 years ago 16% of the population was over 65 and 1.2 million, of a total population of just over 60 million, were over 85 years of age.[2] Current United Nations projections predict the population of over 80s will double by 2050, representing 10% of the total population in developed countries. There are some signs this inexorable rise in life expectancy may have peaked. For the first time in 50 years Spain reported a fall in life expectancy,[3] a finding repeated in some parts of the US.[4] These recent declines have been attributed to familiar factors accounting for poor health: obesity, tobacco and other preventable risks.

Nevertheless, the post-war increase in longevity means many more elderly people present to critical care than previously. This greater longevity may be attributable to improved diet and better lifestyle decisions, but is also explained by improved disease management; however, the resultant gain in survival is at the price of living with morbidity. Not only are there more elderly patients but also they have more significant co-morbidity and thus a greater likelihood of developing a critical illness.

These societal changes are reflected in the ICU demographics. In Australia and New Zealand 13% of ICU admissions were over 80 years old and the numbers had been increasing by about 5% per annum between 2000 and 2005.[5] Unsurprisingly, the chances of being admitted to ICU are somewhat related to resource availability. In 2005 the number of ICU beds per 100 000 population was 3.3 for the UK, 7.8 in Australia, 24 in Germany and 20 in the USA.[6] A study comparing the USA with the UK in terms of hospitalisation and the elderly found that 47% of British over-85s died in hospital, whereas this figure was only 31% in the US; however, only 1.3% of these patients received intensive care in the UK compared with 11% in the USA.[7] Of all hospital discharges, only 2.2% of patients had received intensive care in the UK compared with 19.3% in the USA.

Approaching the problem from a different direction is to consider what happens to a whole cohort of elderly people. One such longitudinal study from America following over 1 million elderly patients over a 5-year follow-up period found that over half were admitted to some higher dependency care unit at some point.[8]

THE AGEING PROCESS

Individuals accumulate co-morbidities with pathophysiological consequences as they age – but these physiological changes are both unpredictable and extremely variable across any population. Ageing is the combination of physiological change and accumulated pathophysiology (Fig. 12.1). Examples of physiological

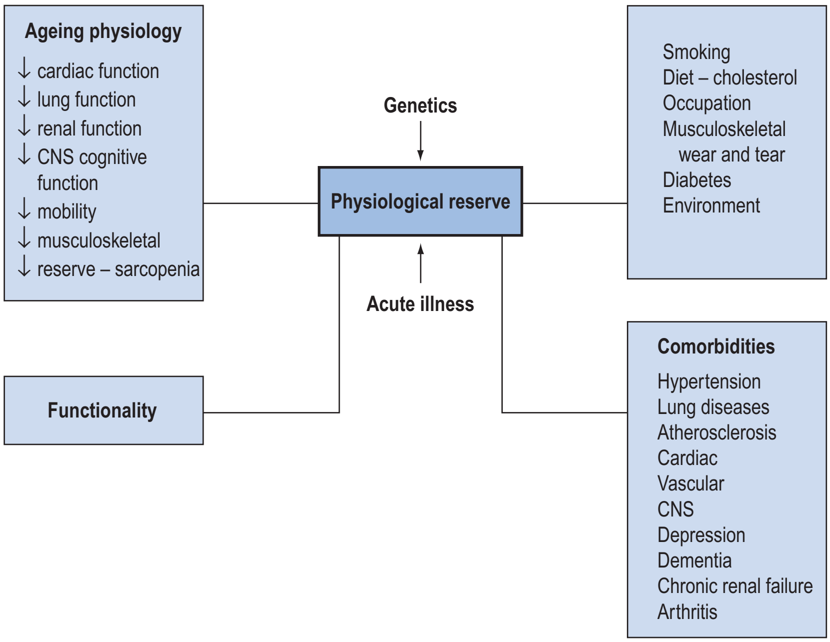

Figure 12.1 Factors affecting physiological reserve.

changes associated with ageing include maximal oxygen uptake, cardiovascular function, muscle mass, tissue elasticity, memory and reaction time, but there are many more.[9]

THE ORGAN SYSTEMS

Each organ system undergoes age-related declines but, in addition, there are specific disease-related organ alterations leading to a net impairment of organ function. A brief overview of changes associated with age and the impact of commoner co-morbidities follows.

CARDIOVASCULAR CHANGES

The heart has reduced contractility and overall mechanical efficiency.[10] This is caused by:

- altered connective tissue compliance due to interstitial collagen being laid down
- reduction in myocyte numbers
- valve hardening and sclerosis, which can affect function
- fibrosis and cell loss in conduction pathways impairing conduction
- deterioration in the sinoatrial node
- ventricular hypertrophy with slower myocardial relaxation.

The result of these changes is a reduction in arterial compliance with an earlier return of the reflected wave in systole. Normally, cardiac pulsatile energy is absorbed at arteriolar segmental level in the young but not in the elderly. Aortic impedance increases and higher blood flow organs show familiar signs of microvasculopathy. This, coupled with the tendency for pulse pressure to rise with age, means that ventricles hypertrophy and cardiac work increases. The resultant increasing oxygen demand occurs against a background fall in diastolic coronary blood flow with ventricular hypertrophy.

Both contraction and relaxation phases are slower. Diastolic filling time is reduced placing an extra emphasis on the atrial component to maintain this filling resulting in a reversal of the E/A ratio (early to late diastolic-filling velocity). Subsequent atrial dilatation is more likely to lead to atrial fibrillation, significantly compromising ventricular filling. The smaller end-diastolic volume is poorly tolerated and impaired cardiac performance ensues.

In addition to these changes, coronary flow reserve is limited, blood vessels are less easily dilated and there is a chronically elevated basal sympathetic tone. Baroreceptor reflexes are impaired and there is decreased sodium conservation.

In summary, the main ageing changes are myocardial and vascular stiffening, with impaired cardiac and vascular compliance. The blunted sympathetic responses produce the 'hyposympathetic heart' with a tendency to increased end-diastolic volume. Additionally there is an age-related reduction in cardiac contractility. Overall cardiac reserve and flexibility of response are reduced, but are usually more than able to deal with

Box 12.1 Cardiovascular ageing

Cellular changes: reduced excitation contraction coupling, calcium homeostasis, myocyte function and increased atrial natriuretic peptide
Decrease in myocytes, altered connective tissues, increased ventricular wall size
Reduction in conductive tissues and numbers of sinus node cells
Decreased contractility, reduced ventricular compliance, increased ventricular filling pressure, blunting of β-adrenoceptor responsiveness, reduced coronary flow reserve
Stiffer arteries, reduced elasticity
Thicker media and intima
Alterations in autonomic tone with reduced β-adrenoreceptor-mediated vasodilatation; reduced NO activity
Reduced heart rate, increased end-diastolic volume, increased stroke volume, reduced peak values for ejection fraction, cardiac output
Impaired conduction, atrial fibrillation
Clinical effects: more arrhythmias, hypertension, reduced exercise tolerance, dyspnoea and heart failure

the normal physical requirements of the elderly – though not with more excessive demands (**Box 12.1**).[10,11]

ACQUIRED CARDIOVASCULAR DISEASE

Atherosclerosis is detectable much earlier in life and starts to become relevant around 40 years of age in males and after menopause in females. Forty per cent of deaths over the age of 65 are cardiovascular and this increases with age. Diabetes, smoking, poor blood pressure control and high cholesterol all increase the risk of death from cardiovascular disease and most become more common with age.[12] Myocardial infarction carries a higher mortality in the elderly and the risk associated with interventional treatments is also higher.[10,11] The Framingham study showed that 40% of myocardial infarctions in those over 75 were silent.[13] In addition, arrhythmias such as atrial fibrillation are more common as a chronic feature in the elderly but most particularly affect the postoperative patient. In one study, 22% of over-70-year-olds developed postoperative atrial fibrillation.[14] When it does occur patients may be more at risk from hypotension, cardiac failure and myocardial infarction. The commonest cause of death amongst the over-85s in the postoperative period is myocardial infarction.[15]

RESPIRATORY

Lung function decline starts at around the age of 35 years. Muscle function is impaired by a combination of reduced fast twitch fibres and muscle atrophy such that between the ages of 65 and 85 there is a decrease in maximum inspiratory pressure, maximum voluntary ventilation and FEV1. Impaired diaphragmatic strength impacts on force of coughing. Degeneration of elastic fibres in the lung parenchyma leads to air space enlargement. Chest wall compliance is reduced and a rise in closing volume results in increasing V/Q mismatching. This whole effect has been termed ‘senile emphysema’ and is often accompanied by age-related β-receptor dysfunction.

Gas transfer is also affected – DLCO declines with some impairment of oxygenation (about 0.5 kPa/decade) but no discernible effect on carbon dioxide clearance. Both the hypoxic and hypercapnic respiratory control responses are blunted. Exercise capacity, as shown by V_{max}, declines by about 1% per year after the age of 30.[15–17]

Less direct intrinsic and extrinsic changes also occur that will impair respiratory function. Diminished antioxidant defences have been observed and bronchial lavage sampling shows changes in both immunoglobulin and CD4/CD8 ratios implying chronic antigenic stimulation. There is also an increasing age-related burden of problems such as nocturnal gastroesophageal reflux, kyphosis, vertebral collapse and sleep apnoea. The likelihood of environmental exposure to agents with the potential to cause lung damage, most particularly tobacco smoke, increases with age.

Hence it is predictable not only that more elderly patients will require respiratory support, but also that ventilatory weaning is going to be more challenging in this group. Mortality is also likely to be higher as compared with younger populations. An American study confirms that the likelihood of requiring ventilation does increase with age, with an estimated 10% chance in the over-75s.[18] Amongst those who are ventilated mortality in the over-70s is nearly double that in the under-40s,[19] and there is a high 3-year mortality in those discharged from ICU with 57% of deaths occurring early after discharge.[20] This bleaker picture is offset to some extent in those with chronic obstructive airways disease; patients with acute exacerbations have a lower mortality at 28% as compared with other causes of respiratory failure. Nevertheless, even amongst ICU survivors in this group, the extent of premorbid problems and the need for ongoing care at discharge dictates outcome; if they were not fit to go directly home then mortality is higher[21] and a high proportion will still need help with at least one activity of daily living, and the quality of life scores are low – though not necessarily lower than they were premorbidly.

RENAL

Kidney size becomes smaller with age due to a reduction in the number of nephrons; 20–30% of glomeruli become sclerotic and glomerular filtration rate may diminish by 50% by 80 years of age. However, this is neither consistent nor predictable.[22] Not only does

creatinine clearance start to decline from the fourth decade of life but renal blood flow also decreases by about 10% per decade. Tubular exchange of sodium and hydrogen ions is also reduced, with impaired ability to handle fluid loads and academia. Rarely is this ever seen as a clinical or biochemical entity, but it does represent a reduction in reserve capacity and manifests only when acute stressors are applied. In the elderly, the competing needs of the kidney versus the heart make the treatment of incipient failure of either organ problematic, and failure of one organ can cause failure of the other – this has been termed 'cardiorenal syndrome'.[23]

The risk of developing acute renal failure increases with age and is especially associated with co-morbidities such as cardiac failure and renovascular disease and acquired preconditions such as known nephrotoxic drugs, surgical interventions and sepsis. Obstructive uropathy may be a consequence of the increasing prevalence of prostatic disease. Many drugs have been implicated, but non-steroidal analgesics and ACE inhibitors stand out. Surgery involves acute changes to blood pressure and volume status, but carries the additional risk of abdominal hypertension.

There is an attributable mortality associated with acute kidney injury, though it is difficult to tease out. It appears that this may be similar between the young and the old[24] and has been variously quoted at between 15 and 40%. The outcome from acute renal failure is determined by cause and prior functional status, with drug-related renal failure doing better than most other causes. The mean survival of octogenarians after an episode of acute renal failure was 19 months, but complete recovery of renal function occurs in just over half the survivors.[25] In one study, only 3 out of 23 biopsies of acute kidney injury showed evidence of acute tubular necrosis.[26] Those with pre-existing chronic renal failure are seven times more likely to progress to long-term dialysis.[27]

A secondary but important effect in the elderly is that there is often a reduced ability to excrete drugs. The consequence may be prolonged half-life (by a factor of 1.4), altered volumes of distribution (+24%) and reduced clearance.[28] This is probably a source of excess morbidity in the elderly.

LIVER

This is relatively unaffected and has huge intrinsic reserve so that a reduced mass of up to 30% at 80 years probably has little effect, other than loss of reserve. There is a tendency to reduced liver blood flow by up to 40% at 80 years and also reduced metabolic function, in particular demethylation and the production of cholinesterase. It may have some effect on drug handling, but is rarely of clinical relevance.

It is acquired liver disease (most commonly cirrhosis) that is the potent predictor of mortality and this has a peak age of presentation in the sixth or seventh decades of life. Nevertheless, age itself is not a poor prognostic indicator in the context of patients with cirrhosis requiring intensive care.[29]

CENTRAL NERVOUS SYSTEM

There is often some decline in cognitive performance with age, though this is contentious. Memory loss is apparent in 10% of those over 70 years of age and about half of these are due to some variant of Alzheimer's disease. This incidence doubles with each decade.[9] The neurocognitive decline is multifactorial but is associated with cerebral vasculopathy, decline in sex steroids, neurochemical alterations such as melatonin and sleep disorders, which are common in the elderly. Dementia has strong associations with cerebral vascular pathology and strokes, but previous head injury is also important. A new era of dementia treatment is imminent and may alter the ICU perspective about the irreversibility of this condition.

Unsurprisingly, patients with neurocognitive decline are much more likely to experience delirium, which is defined as 'an acute confusional state that occurs in the face of an underlying organic aetiology'. It is distinguished from dementia both by the speed of onset and by changes in the level of consciousness. Up to two-thirds of patients aged over 65 years experience delirium in hospital and, in the ICU, one-third of patients are admitted with it and one-third develop it following admission.[30] Clinically, it has a broad spectrum of presentation from inattention, disorientation and agitation through to apathy, immobility and depression. Coma, sedatives and infection are risk factors but other pharmacological agents, noise, light and other sleep-disturbing factors may all be important.[31] It is common after major surgery and trauma, occurring in up to 60% of patients after hip fracture. Many ICU patients develop delirium and in some it will persist as cognitive dysfunction for years. It lengthens hospital stay and is an independent predictor of 6-monthly mortality.[32]

Age is a risk factor for persistent psychological issues and part of this may be related to post-traumatic stress disorder.

Psychological assessment of the elderly post intensive care is in its infancy. Delirium is common and often persistent. The existing tools for assessing delirium are the Confusion Assessment Method for ICU (CAM-ICU) and Intensive Care Delirium Screening Checklist (ICDSC). An ICDSC score of more than 4 correlates with both increased mortality and, in survivors, persistent cognitive dysfunction. More recently the 10-risk-factor assessment tool PREdiction of DELIRium in ICu patients (PRE-DELIRIC) has been validated for ICU.[33] Awareness of the problem should lower the threshold for diagnosis and then these scores, which have been hard to implement, may be used more widely. Anecdotally, the families of elderly patients discharged home often

report behavioural and other changes that imply long-lasting sequelae.

METABOLIC

Over the age of 70 there is a tendency for weight loss with a general change in body composition, leading to increased fat and reduced muscle mass. This sarcopenia is manifested by a 30% reduction in main muscle group strength by the 7th decade of life.[34] With less musculoskeletal activity, there is less energy use, less heat production and a reduced calorie requirement with a 2% decrease in basal metabolic rate (BMR) per decade. Protein requirements stay broadly the same.

Malnutrition is common and calorific intake is often inadequate. This 'anorexia of ageing' is multifactorial and is not just psychosocial – there are some fundamental physiological changes: early satiation is common and gastric emptying is delayed with the feeling of fullness suppressing ghrelin thereby reducing appetite, as do raised cholecystokinin levels, which are also common. Dehydration and micronutrient deficiencies are also frequent; loss of water-soluble vitamins such as thiamine with diuretic therapy, folate and vitamins A, C and E deficiency and vitamin B12 deficiency due to atrophic gastritis and reduced intrinsic factor secretion.[35]

Weight loss, frailty and reduced functional capacity will predispose to morbidity, complications, survival and in survivors reduce the ability to regain independence.

SPECIAL CONSIDERATIONS

In many ways the elderly have the same requirements as any other intensive care unit patient. The lack of functional reserve has been described above under the relevant organ or physiological system headings, but there are some other areas that require special consideration.

PHARMACOLOGY

There are marked changes in pharmacokinetics and pharmacodynamics in the elderly. The impaired ability of the kidneys to excrete drugs influences drug half-lives, which may be prolonged. The volume of distribution may also either increase or decrease depending on the drug and changes in body composition.[28] For example, the aminoglycosides may not only achieve higher concentrations than predicted through distribution changes, but also remain higher for longer due to impaired excretion. NSAIDs may have profound and potentially toxic effects by the potent combination of a relatively smaller volume of distribution and the possibility of relative dehydration producing high drug levels; the associated drug-related inhibition of the prostaglandins would promote renal vasoconstriction, reducing renal blood flow and resulting in renal toxicity.

There may be changes in sensitivity to drugs, partly through altered pharmacokinetics as described, or through interaction with physiology such as the decline in sensitivity to beta-adrenergic agonists and antagonists with age. By a similar mechanism the incidence of orthostatic hypotension with antihypertensive drugs increases. The central nervous system, however, becomes more sensitive to centrally acting drugs.

Fluid management must incorporate some general considerations. These include the potential presence of both cardiovascular and renal impairment (cardiorenal syndrome), a reduced flexibility in cardiac output and an increasing dependence on alterations in systemic vascular resistance. This, along with changes in body composition, may alter fluid distribution. However, it is unpredictable across the population and so should be assessed in the individual.

The biggest single problem in the pharmacology of the elderly is poly-pharmacy. Elderly patients will often be on a panoply of medications depending on their chronic health problems. Most drugs have side-effects and interactions and, as the number of medications increases, so too does the likelihood of complications from their use – especially when the patient is ill. The classic example is antihypertensive drugs in the elderly causing postural hypotension. There is a literature relating to the role of poly-pharmacy in hospital and ICU admission with two very different mechanisms: firstly, the drugs being the source of the problem and, secondly, the impact of inadvertent discontinuation of important medications.[36] It is not a minor issue and an important part of the assessment of the elderly should be rationalisation of medication.

SURGICAL OUTCOME

Increasing numbers of elderly patients are having increasingly complex surgery performed upon them. Both operative mortality and postoperative complications are higher in the elderly and again relate to existence of co-morbid disease and lack of physiological reserve. The fitter the patient, the less likely he/she is to experience complications and this is true for both cardiac and non-cardiac surgery.[37, 38] One study in the over-80s showed that 6-month mortality rates after ICU discharge were 30% for planned surgical patients compared with 76% for emergency surgical patients.[39] Elderly patients presenting as emergencies have been eloquently described as 'a heterogeneous cohort of both potentially treatable patients and those who are dying'.[40] Distinguishing the treatable from the futile is difficult across all age groups but particularly so in the elderly where limited life expectancy is usual and severe but unrecognised co-morbidity may exist. Committing patients and their families to emotional and physical hardship is clearly justifiable with a good outcome, but

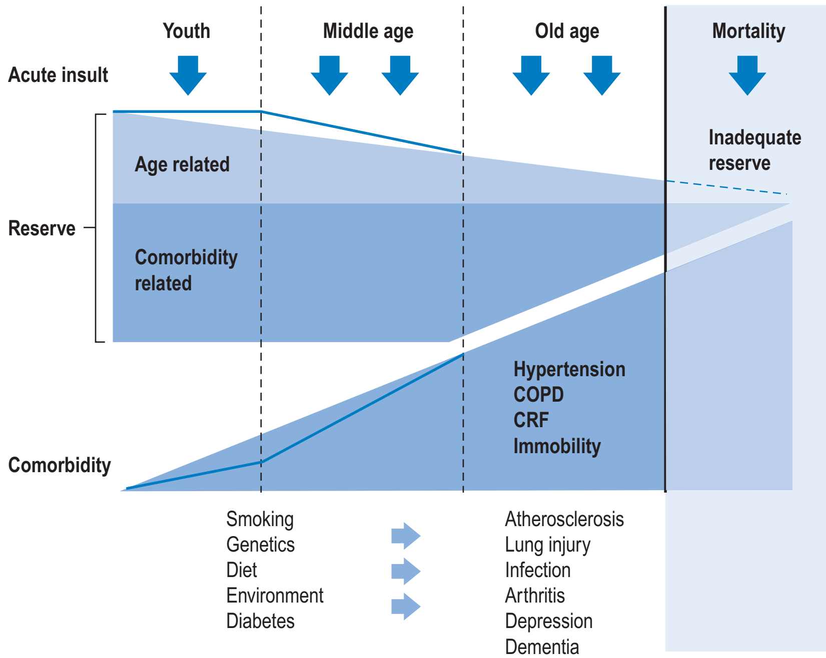

Figure 12.2 Factors affecting ICU outcome. COPD, chronic obstructive pulmonary disease; CRF, chronic renal failure.

far harder to defend if the outcome was never likely to be good. The patient's wishes or preferences should ideally be taken into account, but frequently that is not possible. This is an area of practice that has not been studied but anecdotally is very poorly managed.

ICU OUTCOME

How the interaction between age itself, the severity of the acute illness, or the accumulated co-morbidities and declining functional status due to ageing affects ICU outcome is uncertain (**Fig. 12.2**). APACHE scoring attributes only 7% of the outcome predictive power to age alone. Nevertheless, in some studies of ICU admissions, increasing age does appear to be independently associated with higher 30-day hospital mortality.[41] One study suggests that, for the over-80s, half will not survive ICU but half the survivors will be alive 2 years later.[42] Intuitively, the pre-morbid functional status and presence of co-morbidities should significantly affect ICU outcome. Even supposedly soft indicators such as coming from a care home was associated with higher in-hospital mortality and the medium-term mortality at 6 months is also increased if the patient is discharged to care facilities.[20] In a study of over 15 000 elderly patients compared with non-elderly ICU admissions, the elderly were more likely to have greater co-morbid illnesses and higher illness severity scores, which led to a higher ICU mortality and these patients were more likely to be discharged to either rehabilitation or long-term care.[43] Conversely, other studies have failed to find an association between outcome and pre-existing co-morbidities or functional status.[44]

Age itself is not a useful prognostic indicator and its use as a surrogate for general status is unpredictable. Nevertheless, it is possible to conclude that the outcome for elderly patients admitted to ICU is poorer than for younger patients, but that outcome relates to the pre-morbid state, the severity of the acute illness and the presence of an underlying fatal illness, as in other populations.[42]

Quality of life is probably a more relevant factor than survival. Most patients will have significant functional disability on ICU discharge, which may improve although the evidence is difficult to interpret. In general, those experiencing major acute events with little pre-existing co-morbidities report a substantially lower quality of life afterwards compared with those with significant pre-existing co-morbidities and this is most probably due to relatively lower expectations in the latter group. It is a contentious area with some studies showing no real impairment in quality of life whereas others show significant decline in quality of life.[45]

Probably the best indicators of real outcome for the elderly are measures such as returning home, which has rarely been assessed but is often a very important consideration for the individual. Conti and colleagues assessed this with the results seen in **Box 12.2**; this approach is probably more relevant than mortality figures.[46]

In the future there needs to be more focus on both physical and mental functionality as an outcome

Box 12.2 Factors that influence elderly patients getting home from ICU[46]

Important factors
Over 75 years of age
Neoplasia
Chronic heart failure
Neurological or neurosurgical cause for admission
Trauma
Respiratory failure
Cardiology
Neurological complication
Cardiological complication
Haematological complication
Surgical complication
Less important factors
Planned surgery
Visceral surgery
Chronic renal disease
Living alone

From Conti M, Friolet R, Eckert P, Merlani P. Home return 6 months after an intensive care unit admission for elderly patients. Acta Anaesthesiol Scand 2011;55:387–93, with permission.

measure. Patients need to be not only alive but also have reasonable functional status and ideally be able to return home.

ASSESSMENT FOR ADMISSION

Premorbid functionality and the severity of co-morbid illnesses is of paramount importance when deciding on suitability for admission. This must be put in the context of the acute insult and an analysis of whether the disease process is reversible and if the patient is salvageable. If not then the application of intensive care is likely to impose a physical and mental burden on the patient and their family that cannot be justified by the likely negative outcome. Objective decision making is problematic and it is worth noting that physicians may overestimate the mental and functional status of patients accepted for admission and underestimate it for those whose admission is rejected.[47] Age has little role to play in this decision other than its association with physiological decline and the acquisition of co-morbidity. It is also worth remembering that many elderly patients will have one form or another of advanced directive.

HISTORY

This should involve speaking to the patient or, if impossible, to their relatives to make an assessment of their previous functionality physically and mentally. Establish whether co-morbidities are present and if so how severe. Determine whether the patient is living at home or in a home and how independent he/she is. Living in a nursing home may sometimes, but not always, be a surrogate for significant functional impairment.[43] In the elderly nursing home population anaemia, cancer, heart failure, renal failure and COPD are all related to poor 1-year outcome. For those with previous hospital admissions a history of ventilation is also a potentially important feature. There is a need to know the physical and mental trajectory over the last few months or years, which may indicate significant functional decline. Details relating to level of activity (house, room, chair or bed bound) are powerful indicators (**Box 12.3**).

Box 12.3 History

Where do they live – at home or in care
Independence – how much support
Mobility – shopping, walking
Memory – confusion, sleeping pattern
Previous hospital admissions – in particular ventilation or chronic renal failure
Co-morbidity – respiratory, cardiology and neurology, but also arthritis and mobility
Drugs
Patient's preferences if known

CLINICAL SIGNS

The general habitus is revealing. Posture, muscle bulk, or more often wasting, and the condition of the skin all help indicate long-term physical well-being or otherwise. Ill-health is a potent cause of self-neglect and so the state of the teeth, the lower legs and the feet are very important indicators. Peripheral oedema and infection indicate potential co-morbidities, while chest wall shape may suggest chronic airways disease. Movement and agility are less easily evaluated in acute conditions, but again some impression can be gained by the factors above. Likewise, mental acuity may be difficult to assess in the acute situation.

All of these come together to provide a picture of the level of normal functionality and the degree of co-morbid illnesses, and how they may be contributing to the acute presentation. Then the acute nature of the presentation needs to be evaluated and its reversibility taken in the context of the other problems. The patient's preferences, either declared or previously informed, are a very important part of this assessment. Most importantly no individual part of this should overwhelm all other considerations and age itself is the least relevant factor.

TREATMENT INTENSITY

Elderly patients now present more frequently, have fewer co-morbidities and are more acutely unwell than in the past. They are also more likely to undergo more intensive treatment and are more likely to survive, although the intensity of their treatment may not match that offered to younger patients.[48,49] The conclusion is that high-intensity treatment is appropriate and can produce good results but careful patient selection is key. In a study that followed more than 1 million elderly patients after a diagnosis of serious illness, half were

admitted to ICU at some point and, of these, two-thirds were still alive 6 months later.[8]

However, 3% of this cohort accounted for 23% of ICU usage.

EXPECTATIONS AND PREFERENCES

Paradoxically the aim of treating the elderly in the ICU may be more attainable than with younger patients as they may already have adapted to a burden of co-morbid disease and disability and have limited expectations when compared with young previously fit patients. End of life increasingly occurs in a hospital setting, despite the fact that 86% of patients would prefer to die at home, and therefore the level of medical intervention that elderly patients would want is relevant. Only 16% would take life-prolonging drugs if they made them feel worse and most would want palliation even if it shortened life. Most would not want to be put on a ventilator to gain a week of life and the numbers were similar if it were for a month of extra life.[50] Of those octogenarians who survive ICU, half declared they would not want ICU treatment again if it were required.[51] However, one must be careful about making assumptions in this group of patients. The SUPPORT study showed a poor understanding by physicians of patients' preferences[52] and further declared that, despite the fact that more than half of over-70-year-olds would want CPR most physicians substantially underestimated this.[53]

In 1999, Singer and colleagues identified the following as being most important to patients:

- receiving adequate pain and symptom management
- avoiding inappropriate prolongation of dying
- achieving a sense of control
- relieving burden on others
- strengthening their relationship with loved ones.[54]

END OF LIFE

Death in ICU is usually through some form of withdrawal. Only 10% of patients dying in ICU die through failed CPR. Limitation of life support is very common, as is either withdrawing or withholding treatment. There is huge variation in practice between countries, not only in the decision process but also in the issuing of 'Do Not Resuscitate' orders, and the modes of withdrawal and withholding treatment.[55]

Patient preferences are very important, as is physician recognition of medical futility. Key to this area of management is a clear view of what ICU is intended to provide, an understanding of whether the goals are achievable and acceptance that subjecting a patient and their family to the unpleasant rigours of ICU in the sure knowledge that it will achieve no useful outcome is unacceptable. These determinations must be made objectively.

CONCLUSION

The APACHE score demonstrates that most predictive power for outcome is derived from the acute physiological condition; a much smaller component was the admission disease, 13.6%, and age only constituted about 7%.[41] The nature of the acute condition and the severity of co-morbid disease play a far greater part than the known physiological changes that accompany ageing, and thus absolute age itself. The reversibility of these factors should guide management, and this approach is the same for any patient of any age. It is more likely that an older patient will have advance directives and so will have already voiced their personal preferences.

A simplistic view is that intensive care entails reversing an acute episode with the intention of returning the patient to the position they were in before that episode, or close to it. The majority of treatment is supportive and provides the physiological reserve they have lost until it can be regained. Those with less reserve will need more support. The patient will invariably need a certain amount of physical reserve to meet the challenges of the treatment and the recovery. The decision to use ICU requires acknowledgement that ICU has negative as well as positive aspects and that it can be a very unpleasant experience with far-reaching sequelae, both physical and mental, for patients and relatives. Justification is provided by a good outcome so it is implicit that the opinion at the time of admission is that full recovery is possible or indeed probable. As in every other population, appropriate use of intensive care can produce impressive results but inappropriate use can be disastrous for the patient and their family. Age itself is not a contraindication.

Health care team in intensive care medicine

Gerry O'Callaghan

The concept of health professionals working in collaboration as part of multidisciplinary teams focused on the requirements of individual patients is a well-established historical tradition.[1] This chapter outlines the benefits and effects of team participation, the characteristics of successful teams and the organisations that foster them in the context of acute health care delivery.

The specific interventions that have been applied to the intensive care setting, the composition of intensive care teams, their function and effect on patient outcome are explored. This overview is not a managerial perspective on the utility of team work in delivering improvements in productivity and quality but seeks to provide practitioners of intensive care medicine with an opportunity to reflect on the variety of ways we work in teams as part of our professional activities and responsibilities.

WHAT IS A TEAM?

> *Men wanted: for hazardous journey, small wages, bitter cold, long months of complete darkness, constant danger, safe return doubtful. Honour and recognition in case of success.*
>
> Sir Ernest Shackleton

The recruitment notice that Sir Ernest Shackleton is purported to have placed in the press in 1914 prior to his Endurance expedition to Antarctica is of interest not solely for its relevance to intensive care medicine, which is undoubtedly also a challenge of endurance, but as an example of the extraordinary power of shared purpose. This is particularly the case when such energy is focused by capable leadership; shared purpose is the foundation of team behaviours and success.

A team is defined as a group of people with clearly defined roles and responsibilities committed to a common purpose or task. The individuals who participate in a team share common values and commit to shared behaviours, for example low-tidal-volume ventilation for ARDS or a full-barrier technique for central venous access. The result of their collective effort is expected to produce more than they could produce working separately. The identity of the team is visible from both within and outside (**Box 13.1**).

It is of value to understand the fundamentals of team dynamics as the heterogeneity and complexity of team composition increase with the increasing array of investigations and treatments for critical illness, emerging roles for non-physician providers and participation by intensive care personnel in roles that extend beyond the traditional physical boundaries of the intensive care unit.

Figure 13.1 illustrates the diversity of individuals and skills involved in caring for critically ill patients. ICU personnel include the medical and nursing staff, allied health including physiotherapists, dieticians, pharmacists and many more. Support personnel include clerks, cleaners and others. External ICU is almost limitless including physicians, surgeons, infectious disease physicians, radiologists and more. Although local factors influence the composition and profile of these categories, the variety and complexity are constant.

The composition of critical care teams has wide regional, national and international variability. Non-physician providers are more common in North America than in the United Kingdom, Europe or Australia where advanced nurse practitioner roles are becoming more common. Such roles are well established in paediatric and neonatal medicine and are often an adjunct rather than an alternative to physicians in training resulting in improved staffing levels and continuity of patient care.[2] More than a quarter of adult academic ICUs in the United States have physician assistants and more than half have nurse practitioners as physician extenders.[3] They have a precisely defined scope of practice, and may order tests, prescribe medications and perform diagnostic and therapeutic procedures under the supervision or on behalf of a nominated responsible physician or surgeon. In a recent review of the impact of non-physician providers on patient outcomes in critical care, there were the following observations.[4]

- Inadequate numbers of qualified intensive care physicians mean that such roles are currently necessary.
- Workforce planning indicates this is likely to remain the case for the foreseeable future.
- There is no evidence that non-physician providers are less safe or effective.
- Non-physician providers contribute important increased capacity in additional areas of intensive care activity such as quality improvement.

The increasing diversity of clinical roles and complexity of therapies (e.g. extracorporeal membrane oxygenation) require that frameworks for improved communication and coordination as well as role delineation have become essential. This view has been endorsed for over a decade by a wide range of professional, academic and government bodies such as The Institute of Medicine, which recommended in To Err is Human, Building a Safer Health System that those who work in teams should train in teams.[5] There is an emerging literature that demonstrates improved outcomes across a range of parameters following implementation of various team-based interventions predominantly using simulation as a platform for improved communication. These innovations are examined later in this chapter.

An explicit team-based approach facilitates continuity of care and effective transfer of information between teams contributing to patient care during the patient's hospital journey. The Australian Commission for Safety and Quality in Health Care describes this transfer of information, accountability and professional responsibility for some or all aspects of care for a patient to another person or professional group on a temporary or permanent basis as clinical handover.[6]

Figure 13.2 illustrates the varying and often asynchronous frequencies of shift changes between nursing, resident and intensive care consultant staff challenging safe and effective continuity of patient care.

The OSSIE Guide to Clinical Handover Improvement summarises the risks to patient safety posed by this high-volume activity as well as providing tools for clinical practice improvement and a comprehensive literature review.[6] Clinical handover is a common cause of adverse events and malpractice claims. It is often of poor quality, infrequently written and generally perceived to be inadequate or unhelpful. A team-based structured approach to handover called the SBAR (situation–background–assessment–recommendation) technique can address these issues effectively.[7]

Much of the language and methodology informing the development of effective teamwork is from a corporate culture that is now being implemented in large health care organisations around the world. The driver for developing effective team-based behaviours is patient safety with strong advocacy and resource allocation from such organisations as the Institute for

Box 13.1 Characteristics of a team

- Common goals
- Shared behaviours and values
- Visible identity
- Clear understanding of roles and responsibilities
- Greater collective than individual effectiveness or potential
- Understanding of shared tools and artefacts such as vocabulary, skills, knowledge
- Mutual trust and respect: solidarity

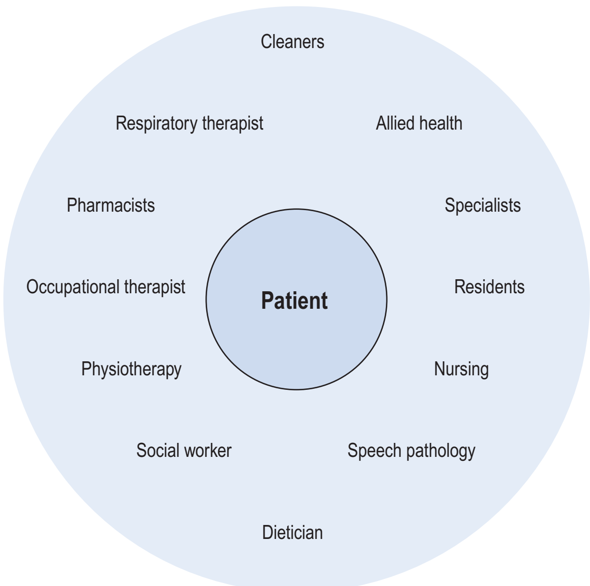

Figure 13.1 The clinical and ancillary care of patients in intensive care is provided by large diverse teams of health care workers. The size, diversity, variability and complexity of these teams make common training in non-technical skills highly desirable.

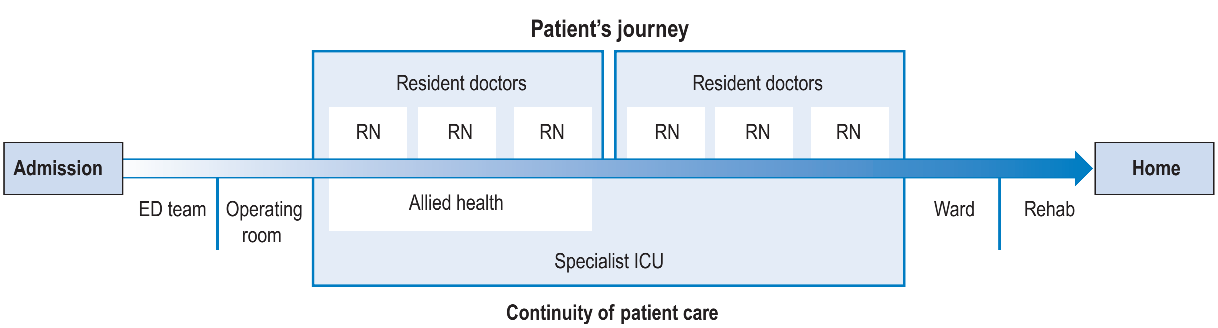

Figure 13.2 Continuity of patient care is the seamless provision of care, transfer of information and communication with relevant stakeholders over time and across multiple locations during a patient's hospitalisation or illness. ED=emergency department; RN=registered nurse.

Health Improvement, the National Health System in the UK, and the Australian Commission for Safety and Quality in Health Care. This derives from the improvements in safety and efficacy demonstrated by team training in the airline industry, the crew resource management (CRM). This is a simulation-based programme that teaches and assesses individual performance of the 'non-technical skills' necessary for effective delivery of complex technical tasks, particularly in high-stress situations. These can be defined as 'the cognitive, social, and personal resource skills that complement technical skills, and contribute to safe and efficient task performance'.[8] The teaching framework has four elements:

- *Situation awareness:* understanding and anticipating the impact of the specific situation on the performance of workers and patient outcome. Examples include requesting further information, confirming the validity of physiological information, checking monitoring, anticipating patients' next steps and confirming this perspective with other team members.
- *Decision making:* including the ability to identify options, incorporating risk assessment and taking time to re-evaluate progress, if necessary recognising failure and changing direction in a timely way.
- *Team work and leadership:* cooperative collaboration in complex task delivery in your assigned role, recognising that you may need to explicitly identify and claim the role that is appropriate to your level of skill and experience. This includes information sharing, seeking assistance, supporting fellow team members and coordinating efforts.
- *Task management:* planning, preparing and prioritising the actions that need to be taken, identifying the resources necessary to achieve the planned tasks and performing them to an appropriate standard.

Tactical thinking is thinking focused on particular tasks. Strategic thinking is a broader consideration of the needs of the patient, team members and organisational requirements and is the responsibility of the team leader.

A training programme based on this approach has been developed for anaesthetists called Anesthetists' Non-Technical Skills (ANTS). Extensive task analysis describing the language and behaviours specific to situations encountered by anaesthetists formed the basis for identifying markers of good or bad performance that could used for assessment.[8] (For details see the website address www.abdn.ac.uk/iprc/ants.)

Rolling out a promising innovation is challenging:

1. It is essential to have a critical mass of course providers who have a sound understanding of the psychology of human performance, the methodology and language of non-technical skills, and the teaching and assessment of colleagues and trainees. Where this is not the case there are unacceptable levels of inter-rater reliability and accuracy.[9]
2. Sustainability of benefit has been shown where training is provided in a similar manner to the CRM programmes in the aviation industry.[10] The authors' recommendation is for a minimum ANTS course length of 2 days to acquire sufficient knowledge and the techniques required. This is an indicator of the organisational support necessary.
3. It provides an insight as to why it is difficult to demonstrate benefit on patient outcomes when few health care providers have the skills or experience necessary to plan and measure the quantum of team building required to address the relevant clinical issue (**Box 13.2**).

Organisational psychology can be used to analyse and assess team dynamics. In one study the communication interactions between 2500 team members for periods of time were reviewed measuring tone of voice, body position relative to other team members, and how much gesturing, talking, listening and interrupting took place.[11] Team communication was categorised in three ways:

- *energy:* how members contribute to a team as a whole
- *engagement:* how members communicate with one another
- *exploration:* how teams communicate with one another.

Team behaviour and patterns of communication were consistent across different contexts and compositions (i.e. different industries including health care workers and a variety of different team sizes). The quantity and quality of interactions can be measured, face-to-face interactions being the most valuable and email or texting the least. Individual talent and reasoning are

Box 13.2 Characteristics of high-performing teams

Leadership that encourages participation from other team members
Effective decision making, clear, transparent, timely and consultative
Open and clear communication
Valuing diversity, welcoming diversity of experience, culture and knowledge
Mutual trust, committing to shared actions and strategies
Managing conflict – dealing with conflict openly and transparently, avoiding the gradual build-up of internal tensions and grudges
Clear goals that have personal meaning and relevance, supported by sharing data and resources
Defined roles and responsibilities – team members understand what they must do and must not
Coordinative relationship, strong bonds between team members supporting frequent interactions
Positive atmosphere, team culture that is open, transparent and positive and believes in the reality of success

Source: www.en.wikipedia.org/wiki/High-Performance.

less important than adopting successful communication patterns.

Successful teams share several defining characteristics:

1. Everyone on the team talks and listens in roughly equal measure, keeping contributions short.
2. Members face one another and their conversations and gestures are energetic.
3. Members connect directly with one another and not just with the team leader.
4. Members carry on back channel or side conversations within the team.
5. Members periodically break, go outside the team and bring information back.

Successful team participation can be learned, and advantage can be taken of the multiple opportunities that present themselves for team working. Critical care physicians are generally expected to take on leadership roles, but few physicians receive any formal training in this area.

A simple checklist can be used for assessing team interactions with colleagues:

- Are my co-workers contributing to ward rounds and patient-centred discussions?
- Do they speak generally or just to one other person?
- Are individuals removing themselves from the group or not facing other team members when they are speaking or listening?
- Am I or the other leadership figures too dominant, speaking too much or too loudly?
- Does everyone get to finish sentences or are people interrupted and cut off?
- Am I (we) happy for any individual team member to speak on behalf of the team?

This final question is a test of mutual trust and respect because it involves accepting reputational risk on behalf of co-workers.

Organisations' attempts to create a high-performance team culture may fail because of:

- insufficient appreciation of the resolve, expertise and resources required to achieve cultural change
- advocacy for team-based training being promotional rather than a full commitment
- provision of insufficient time, opportunity, resources or executive support.

Similar issues have been demonstrated in the implementation of clinical therapeutic guidelines.

NECESSARY OR DESIRABLE ORGANISATIONAL CHARACTERISTICS THAT SUPPORT EFFECTIVE IMPROVEMENT IN CLINICAL PRACTICE AND PATIENT OUTCOMES

Bohmer characterised the four habits of high-value health care organisations[12] (defined as organisations that achieve value in terms of the ratio of long-term outcomes to costs):

1. *Specify and plan in advance:* with decisions based on predetermined explicit criteria
2. *Deliberate design of infrastructure:* including clinical microsystems that align physical environment, business process and clinical pathways in well-defined patient populations
3. *Measurement and oversight targeting:* by predefined metrics, quality and safety goals, which inculcates both accountability and performance
4. *Self-study:* using measurement so that knowledge, data and clinical information can be used not only for assurance of best evidence-based practices but also to identify deviations. Information is shared and not considered to be the property of individuals or departments.

Organisational readiness is a prerequisite to building high-performance critical care teams.

TYPES OF TEAM

A *clinical microsystem* is the most fundamental unit of health care delivery that addresses the needs of a population of patients. It is the dynamic integration of personnel, clinical and support staff, technology, information, care and business processes.[13] Implicit is the participation of all those who have direct patient care responsibilities (**Fig. 13.3**). Participation is compulsory and is the baseline of team participation in the unit, but most participants will also be involved in other team types within this structure. The choice/volition of the

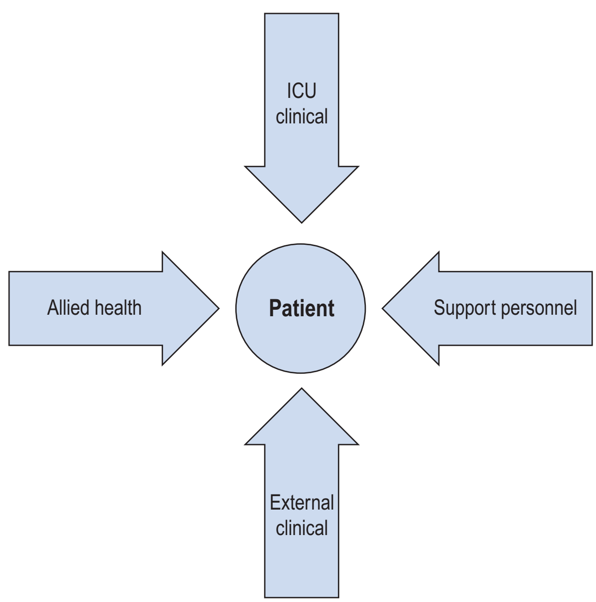

Figure 13.3 Clinical microsystems are the most fundamental units of health care delivery that address the needs of a specific population of patients. This system includes personnel, procedures, business processes and infrastructure.

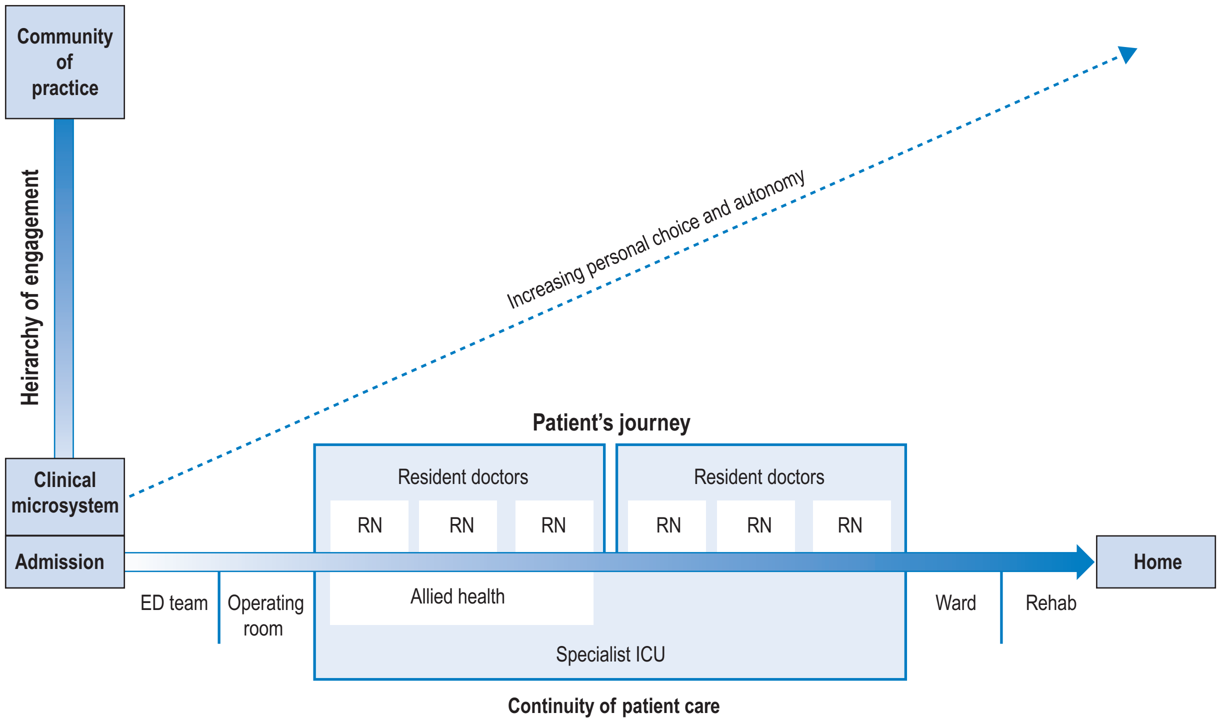

Figure 13.4 The hierarchy of individual integration of team participation represents the relationship between the interests and skills of an individual and the necessary activities that support a clinical microsystem such as an intensive care unit. Activities that are not directly related to patient care provide an opportunity for personnel to choose those activities that are of greatest professional interest. ED=emergency department; RN=registered nurse.

individual within teams is variable. The greater the clinical focus of the team or activity the less choice individuals have in terms of choosing to participate. Resuscitation, diagnosis and treatment are core team activities, while research, safety and quality, administration provide opportunity for choices that align with the interests and expertise of the individual. Collaborations beyond the immediate clinical microsystem in the hospital, professional, interdisciplinary and academic worlds have the greatest degree of choice. Team contexts are relevant to the broad understanding of health care teams.

CRITICAL INCIDENT RESPONSE TEAMS

Medical emergency teams, code and trauma teams need skills designed to meet the crisis, such as airway management, insertion of central venous lines and trauma management. Teams may be nurse or physician led, are highly focused on a single task and often include individuals who interact infrequently owing to the rarity of certain events or the rostering practice. The membership of such teams is highly dynamic, opportunities for training limited and the level of familiarity with local procedures, policies and organisational characteristics varies with the individual team member (**Fig. 13.4**).

Leadership by an easily identifiable authority figure, who has both accountability and responsibility for the outcome, enables the application of well-defined clinical pathways or protocols. This leadership is variously described as top-down, autocratic or transactional[14] and has been demonstrated to improve both process metrics and patient outcomes (**Fig. 13.5**).

ACTIVITY- OR CONTEXT-RELATED TEAMS

These may be described as committees, working groups or parties with variable degrees of formality and stability. These range from ad hoc conversations or correspondence between senior clinicians to formalised adverse event reporting to a committee. The latter has defined terms of reference, meets regularly, keeps records and may be multidisciplinary from both within and outside the ICU and involves clinical governance. They may be temporary, such as implementing a new treatment, or consist of well-established groups responsible for monitoring and communicating clinical outcomes to their peers on a range of clinical indicators. **Figure 13.6** illustrates examples of such clinical contexts.

Critical incident and context teams (see Fig. 13.6) require and benefit from different styles of leadership. Leadership characteristics include inclusiveness, proactive mentorship of less experienced or confident team members, providing a personal example of ethical behaviour and maintaining focus of team members on

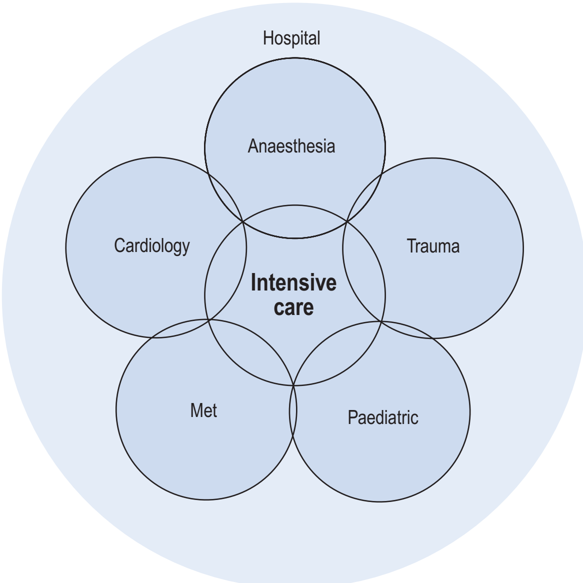

Figure 13.5 Critical incident teams are ad hoc teams of individuals from a range of clinical and professional backgrounds that assemble to meet the clinical needs of a patient experiencing acute physiological deterioration in an acute hospital setting.

Figure 13.6 Context- or activity-based teams are comprised of individuals from a range of clinical and professional backgrounds who are collectively engaged in administrative, educational and professional activities that support clinical care.

the shared goal. This type of leadership is variously described[12] as democratic, consensus driven, empowering or transformative and is associated with improved staff commitment and participation in safety initiatives. The challenge is adequate flexibility to choose the most appropriate leadership style for each situation, adaptive leadership.

Long-term project outcomes with strong external connections require a different type of team. As such teams are informal and self-organising, often created by the commonality of learning behaviours and activities, consolidated through social interactions, they may not recognise themselves as team members. Examples include research collaboration between clinicians working with laboratory-based scientists and other experts, often from disparate geographical locations. The Community of Practice model first described by Wenger[15] can be used to examine this group. The driving characteristics of working collaborations are a shared knowledge or practice domain, workplace-based context of learning and fluctuating levels of participation. Professional development activities combined with social interaction form an ongoing mechanism that supports professional collaborations and exchange of information such as best practice tools, etc. This formal facilitation of social cohesion in professional groups is part of the community of practice model. Increasing participation and avoiding marginalisation are both important in realising and maximising colleagues' potential.

It is useful to reflect on the numerous types of teams to which intensive care practitioners may belong in order to:

- select the most suitable model for the assigned goal
- measure the overall impact on patient outcomes, staff satisfaction or other parameters
- assess and prioritise workload, taking into account the combination of team-based activities occurring in the intensive care unit.

Effective team-based practices are most commonly described in terms of organisational characteristics or leadership responsibilities, but this fails to emphasise the benefits to team members, which are summarised in Box 13.3. These benefits result in improved job satisfaction, which translates into improved staff retention, less sick leave, increased productivity and reduced costs.

SPECIFIC TEAM-BASED INTERVENTIONS AND INNOVATIONS

Broadly there are four categories of intervention that have been applied in critical care areas. These overlap considerably depending on the programme methodology and content.

1. Leadership
2. Team building
3. Simulation
4. Organisational change.

Box 13.3 How team members benefit from team participation

Opportunity to be heard and for effort to be acknowledged
Psychological safety
Clarity of purpose resulting in clear action plans, relevant tools and strategies
Mechanism to resolve conflict and address underperforming co-workers
More positive work environments
Support for professional development
Improved performance in time-critical stressful situations
Situational awareness

Leaders are 'visibly responsible and accountable for achieving the goals of an organisation', and are the people on whom patients and colleagues depend to get things done. The style (autocratic versus democratic) depends on the situation and may change as the situation demands (adaptive leadership). Leadership is the conglomeration of effective behaviours (see Box 13.2) enabling the team in achieving its goal.

In summary, leaders refine and define the team goal, they create a vision and subsequently they include the team in the design of the tools and mechanisms to achieve this vision. They do not avoid hard discussions and difficult decisions; they are honest about the effort and commitment necessary. They create an environment where team members feel secure and are willing to contribute. The culture they create is one of psychological safety, which is important because within teams are hierarchies. Hierarchical discrimination is very variable and has a definite cultural association, so that where there is a high level of respect or fear of authority individuals are extremely unlikely to either challenge or contribute without a specific request or mechanism to do so.

Explicit leadership behaviours such as task assignment, directing co-workers and check-backs of vital signs are associated with fewer task failures and faster instigation of therapies such as intubation and defibrillation in emergency situations. Any group implementation of training or practice improvement processes by definition creates leadership obligations and opportunities. There is no widespread leadership training intervention applied in the intensive care setting, although several studies demonstrate improved outcomes associated with intensive care specialist-led care.[16]

For example, when the impact of multidisciplinary teams on the 30-day mortality of over 100 000 intensive care patients was assessed, intensive care specialist care combined with multidisciplinary teams was associated with a 16% reduction in mortality, which was consistent across patient cohorts and greater severity of illness.[17] This benefit was similar between intensivist-led care or mandatory consult and multidisciplinary care team input, but the greatest reduction was seen when these were combined. The authors postulate that multidisciplinary rounds improve communication, enhance implementation of agreed daily goals and encourage evidence-based care (e.g. pharmacist participation may reduce drug errors). Effective communication may also reduce length of mechanical ventilation and ICU stay.

A combination of team training, coaching and checklists to instigate communication in the operating room impacted on surgical outcomes.[18] There was an 18% reduction in mortality at the hospitals that implemented the US Medical Team Training (MTT) programme compared with a 7% reduction at the control hospitals; subsequently, implementation in over 187 sites in the United States resulted in improved understanding of daily clinical goals following multidisciplinary rounds in the ICU and reduced lengths of ICU stay.[19] The programme requires ongoing support and follow-up at participating sites and mandatory executive support from site administration.

TRAINING

The TeamSTEPPS® training tool is focused on improving patient safety by implementing an evidence-based teamwork system to improve communication and teamwork skills among health care professionals.[20] It has been used in paediatric, medical and surgical ICUs to train acute care teams, reducing times to placing patients on ECMO, and decreasing the nosocomial infection rate.[21] Other team-based initiatives have reduced rates of ventilator-associated pneumonia (VAP)[22] and reduced resuscitation time in trauma situations.[23]

Simulated scenarios can be used to explore, practise and refine the tools of communication, leadership and other team-based behaviours in a clinical context. Simulation may be high or low fidelity depending on the degree of accuracy with which the clinical scenario is replicated. Training may be stand alone, specifically designed and maintained by full-time professional educators or part of a clinical workplace. The important points are:

- participation requires an active choice to collaborate with colleagues
- simulation is an educational tool that has both strengths and limitations
- many common clinical situations in the intensive care setting are suitable for simulation-based training
- most do not require high-fidelity equipment, but do require expert and experienced facilitators.[24]

Using case-based or simulation-based learning, there were significant improvements in leadership, team coordination and verbalising situational information in the intervention group and improved scores for clinical management.[25] Similar results were seen in the paediatric intensive care setting, where most found

participation to be of benefit and with a highly effective impact.[26] The authors indicated that there is not only a 6- to 12-month learning curve in programme implementation but repeated exposure is necessary to achieve meaningful benefit.

ORGANISATIONAL CHANGE

This is the final area of intervention. It includes teamwork, simulation and leadership training but the context in which the team model operates is important.[27] The Integrated Team Effectiveness Model (ITEM) illustrates how organisational contexts, such as processes, goals, structure have a direct effect on team effectiveness. The Breakthrough Collaborative Model uses organisational engagement and team alignment to a particular goal to achieve significant changes in clinical outcomes.[28] Such an intervention resulted in a significant increase in the rate of organ donation as measured by both donor identification and consent for donation. Teams use plan-do-study-act (PDSA) cycles to implement change in local practices supported by a senior clinical leader. Each team is provided with strategies and tools for change and participates in educational conferences, which allows the more successful strategies to be shared and adopted more broadly. These educational opportunities foster team development and identify clinical leaders. Although effective in accelerating clinical change these large-scale interventions are expensive and require widespread government, professional and health care organisation support (**Box 13.4**).

SUMMARY

Team-based innovation in the specific context of high-acuity environments such as the intensive care unit is increasing around the world (**Fig. 13.7**). There is an

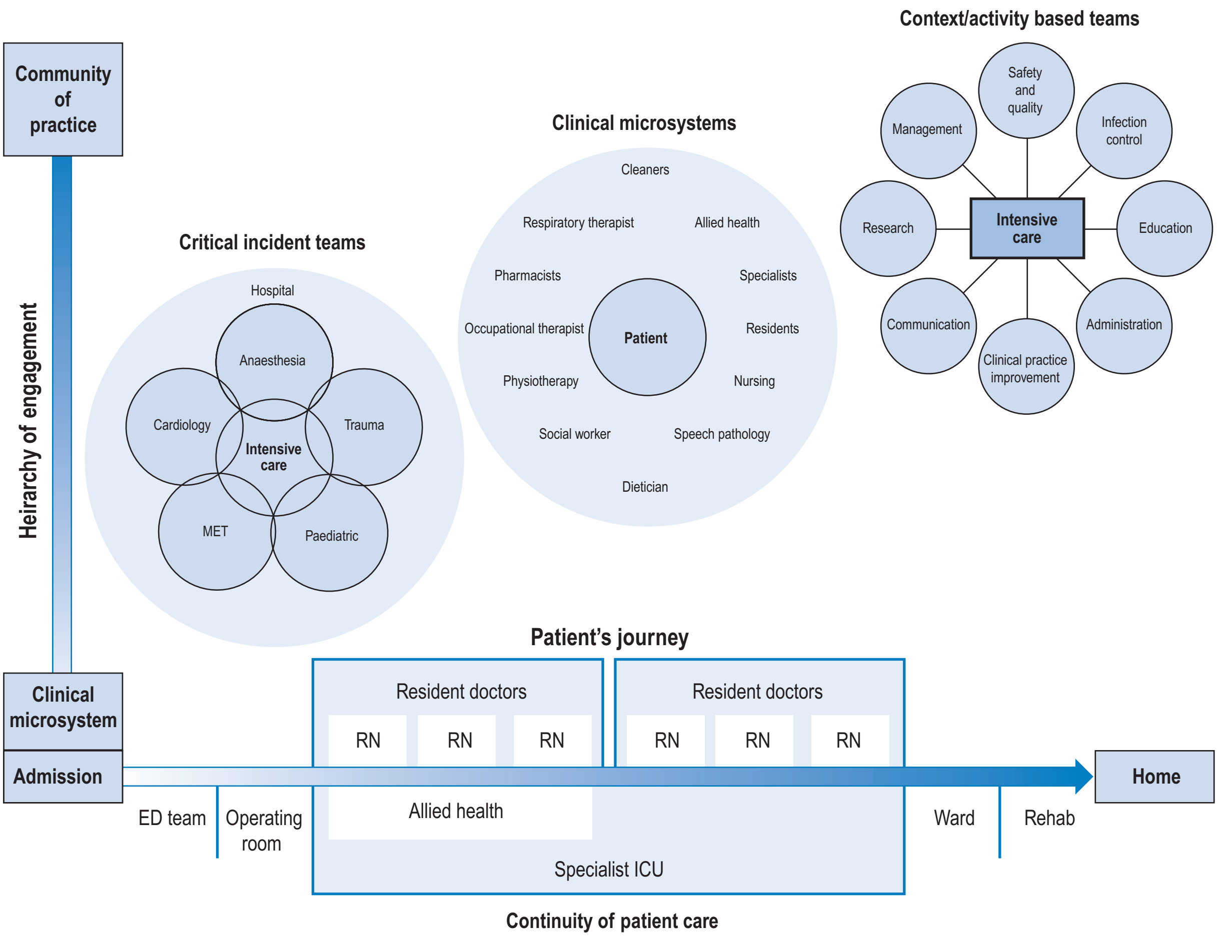

Figure 13.7 Participation in teams which provide specific aspects of clinical care, support professional development and improve quality of care are important articulations of personal preference and autonomy. Such choices are likely to represent important opportunities to increase staff satisfaction and retention and increase system capacity by matching skills and experience with personal interests. ED=emergency department; RN=registered nurse.

Box 13.4 How patients may benefit from team-based health care delivery

Improved continuity of care
Fewer adverse events
Shorter lengths of hospitalisation and mechanical ventilation
Better task delivery in emergency situations
Decreased mortality
Improved family outcomes through better communication

emerging evidence base that supports the following conclusions:

- Team-based interventions result in improved objective and subjective outcomes for patients, health care professionals and provider organisations.
- Well-developed tools, mechanisms and policies are available for the implementation and assessment of such interventions.
- Significant expertise, experience, commitment and resources are necessary to achieve potential benefits.
- The innovation or intervention should be specifically prepared or adapted for the individual circumstances in which it is to be applied.
- Sustainment of improvements in performance requires ongoing maintenance programmes.
- Research to identify the most effective strategies and tools is an appropriate priority for the academic intensive care community.
- Multidisciplinary teams of intensive care health professionals are valuable assets that need to be acknowledged and supported by the organisations in which they work.

Preparing for examinations in intensive care medicine

Carole Foot and Liz Hickson

INTRODUCTION

High-stakes postgraduate examinations in intensive care medicine (ICM) are constantly evolving; as diverse in scope as they are in structure; they have paralleled and fuelled the development of what is now a highly respected independent specialty.

For many specialist doctors, the most difficult challenge of their professional career to that point is their fellowship examination. It is viewed by many as a daunting obstacle that grants a right of passage into a fraternity of consultants who share a common commitment to excellence in managing critically ill patients.

This chapter outlines the rationale for these examination processes and their structure. It also reviews various different strategies that may be of benefit to candidates and also of relevance to their supervisors and mentors.

EXAMINATION STRUCTURE AND PROCESS

At the simplest level, professional examinations aim to differentiate candidates who are ready to progress to a higher level of recognition and responsibility. For example, in Australasia since 1979 a fellowship examination in ICM has served as part of an exit criterion to enable recognition as an Intensive Care Specialist.[1]

The challenge of such examinations is to provide a process with content that assesses multiple domains of a candidate's ability to function as a future specialist. Committees of experts in the field have traditionally worked together to devise examinations that test core specialty knowledge and skills. More recently, the importance of assessing competencies that are of more general relevance to a senior health care professional have warranted specific attention.

The CanMEDS initiative of the Royal College of Physicians and Surgeons of Canada has had a significant impact in some regions, with consideration of how to assess the seven roles of a physician: Medical expert, Communicator, Collaborator, Manager, Health Advocate, Scholar and Professional.[2] These have necessitated the inclusion of questions that test beyond pure science, such as the inclusion of role-plays to assess communication with families and other members of the multidisciplinary intensive care unit team.

An evidence-based approach to examinations is now also recognised to be important. Those responsible for credentialing specialists have the challenge of determining how to consistently provide examinations that have high levels of reliability and validity whilst remaining feasible. Issues such as examiner training, standard setting and calibrating, quarantining of candidates on the day of exams, ensuring sufficient exposure to different components of an exam to ensure adequate depth and breadth of testing and transparency of information about the structure and expectations of candidates during examinations are all important.[1, 3] Logistic considerations are of increasing importance, as the numbers of candidates pursuing specialty certification in ICM get bigger and the potential to compromise the quality of the examination process due to feasibility issues is significant. How to optimally examine clinical skills so that the best representation of workplace performance is determined is the subject of ongoing research. For example, when testing a procedural skill (management of a blocked tracheostomy tube) using a simulation as compared with a written format, it was identified that a significant number of critical errors were revealed with simulation that were not detected in a written answer.[4]

Multimodal assessment is now common in ICM examinations. The College of Intensive Care Medicine of Australia and New Zealand fellowship examination utilises a combination of written short-answer questions, vivas that include a communication station with an actor and a procedural skill station, as well as a clinical examination with 'hot cases' involving live ICU patients. The European Diploma in Intensive Care (EDIC) examination process consists of multiple-choice questions, vivas and clinical cases, although this will change to OSCEs shortly. The British Diploma consists of multiple choice questions, structured orals and OSCEs.

DIVERSITY IN ICM TRAINING AND EXAMINATION PROGRAMMES

At a global level there remains great variation in the evolution, practitioner certification and the practice of the specialty. In Europe alone, it was recently concluded

that there is 'considerable diversity in pedagogic structure, processes and quality assurance of ICM' and there is 'no harmonisation among European countries'.[5]

The CoBaTrICE (Competency-Based Training in Intensive Care medicine) collaboration is committed to developing an internationally relevant curriculum.[5] The Educational Committee of the WFSICCM (World Federation of Intensive and Critical Care Medicine) supports the development of a common competency-based approach that 'permits diversity of training methods while creating a common outcome: doctors with a universal set of knowledge, skills and attitudes essential for a specialist in ICM'.[6] Although this remains a logical and worthwhile goal that could facilitate and help maintain a high standard of ICM practice, there remains a multitude of political, cultural and financial barriers to achieving this.

A lack of internationally relevant standards is also an obstacle for trainees and specialists wishing to gain experience in different countries or to relocate. It is well described that international medical graduates are at increased risk of experiencing difficulties in passing specialty examinations.[7] The reasons for this are not well described, but are likely to include language barriers, variations in practice standards between countries, isolation from training environments and a lack of knowledge and preparation regarding local examination processes.

GLOBALLY RELEVANT ISSUES REGARDING PREPARATION

Candidates approaching postgraduate examinations spent significant amounts of time preparing for these examinations and universally find the process stressful and for many there is a detrimental impact on their personal lives.[8] Never before has there been such a variety and awareness of strategies to assist the process of exam preparation. There is a paucity of literature regarding which of these many approaches trainees find of greatest utility. A recent survey of emergency medicine specialist trainees found that the most highly valued resources were: attempting practice questions, private study, small group work, a mock examination and access to a local trainer involved in exam preparation. Training courses/workshops are also well received.[9]

PREPARING ALONE

PUBLICATIONS

Training bodies commonly publish a list of recommended books and journals that may be of highest yield to candidates. Books such as this one are highly valued as they distil a vast body of literature into a highly condensed format with identification of relevant evidence underpinning critical care medicine.

Books now exist that focus more specifically on examination processes, providing advice on how to prepare for individual components and some also on how to approach the process in general (e.g. Examination Intensive Care Medicine[10] targets all of the clinical components of the Australasian CICM, EDIC and traditional UK diploma examinations).

Other books, on subjects such as critical care radiology, ECG interpretation, echocardiography and evidence-based medicine/statistics, were written to assist a wider audience but serve as great resources for exam candidates.

PRACTICE QUESTIONS

Training bodies may release past papers and repetition of questions is not uncommon. Some trainers recommend *question mapping*, whereby past papers are analysed to try to detect patterns in topic and style that may assist in predicting future questions. Questions that are answered poorly in an individual exam may be followed by retesting in subsequent ones.

Practising questions under testing conditions, with strict attention to time, may develop candidates' technique, identify gaps in knowledge and serve as variety in study methods. Specific strategies have been suggested for tackling multiple-choice papers that vary with the question type and include encouragement for intuitive guessing when negative marking penalties for incorrect answers are not used. Accessing banks of past questions is helpful (e.g. Multiple Choice Questions in Intensive Care Medicine[11]).

ONLINE RESOURCES

There are a myriad of websites that provide a wealth of material that may assist knowledge acquisition as well as focus on specific regions' exam processes. One of the major difficulties for trainees is to filter through the vast offering and identify reliable information most relevant to their context. It is important to appraise website content, but also authorship validity and the organisation of material when making an evaluation on the potential utility of a source. A considered approach analogous to critically evaluating other forms of medical literature is helpful. See **Box 14.1** for an example of one of the most comprehensive member-only websites currently on offer.

PREPARING WITH OTHERS

LOCAL/REGIONAL TRAINING PROGRAMMES

Coaching for examinations is typically part of a well-structured training programme. The degree of organisation and format of such initiatives varies widely from single institution to regional approaches. In countries where ICM training is well established such processes are well developed, whilst in others the situation is nascent. The situation is rapidly changing in some areas (**Box 14.2**).

Study groups formed from candidates working together in local areas or within large departments are

Box 14.1 Crit-IQ

Todd Fraser, Neil Orford and Kevin Murphy established this in 2008. It began as a training tool for intensive care trainees who were in the process of taking the Joint Faculty of Intensive Care Medicine fellowship exam. It aims to provide a high-quality, interactive, independent medical educational resource to help individuals learn, pass exams and stay up to date. Crit-IQ continues to support and assist organisations and individuals, particularly in developing countries. It is a comprehensive, up-to-date, interactive web-based learning platform for critical care doctors of all levels. It comprises learning modules, podcasts and vodcasts, a journal club, echocardiography and ultrasound learning components, a data interpretation database as well as exam support for trainees at various levels. It has developed into a useful resource for all practitioners of critical care, from anaesthetists to emergency physicians to general physicians at all levels of experience.

About Crit-IQ. Online. Available: http://www.crit-iq.com.au/about.cfm.

Box 14.2 TEaM ICM[12] (Trent and East Midlands ICM training programme)

The move by the new Faculty of Intensive Care Medicine (FICM UK) to approve dual and stand-alone training posts in ICM, allows for ICM trainees to be identified early, guaranteeing a minimum of 5 years of training opportunities. Not all of this training will be in direct ICM posts and suggests that there is an opportunity to model formal ICM education on a long-term commitment to the ICM trainee, rather than to concentrate education into ICM training periods only. A prolonged programme can encourage the sharing of ideas and experiences, and allows the development of a peer group, important for the formation of a cohesive and cooperative group of future colleagues.

The Trent and East Midlands ICM training programme, currently into its seventh year, operates a 5-year rolling syllabus that includes all regional ICM trainees, regardless of which specialty or hospital they are attached to, ensuring that a trainee is regularly exposed to ICM educational initiatives include learning days with lectures, quizzes, debates and field trips (e.g. visits to different units and to the coroner), online discussions and a website with various resources.

Courtesy of Dr Dale Gardiner – Implementing a regional training programme in intensive care medicine. The Royal College of Anaesthetists: Bulletin 2010;61:46–8.

of benefit to some individuals. Benefits may include mutual support, sharing of resources, division of labour in preparing study notes including answers to previous questions, as well as practising exam components together.

COURSES

Opportunities for trainees to attend courses offering concentrated exam preparation exist in various countries. For over a decade, candidates approaching their fellowship examinations in Australia have commonly attended at least one of the well-known courses that offer mock examination experiences with feedback (**Box 14.3**). More recently, additional courses have targeted those in earlier stages of their preparation.

Box 14.3 Australasian Fellowship examination courses

Australian Short Course on Intensive Care Medicine (also known as 'Tub's Course' after Lindsay (Tub) Worthley who developed the initiative)*

Numbers are limited and it is specifically aimed at trainees sitting their CICM Fellowship examination within the same calendar year. Prospective candidates must have their supervisors of training attest to their suitability as significant pre-course preparation is expected. It consists of tutorials on the written component, vivas and clinical ('hot') cases, simulating the entire exam process. The 28th 3-day course was held in Adelaide this year (2012).

Brisbane Intensive Care Medicine Course**

Courses have been evolving for over a decade and three components are currently offered:

Data Interpretation in Acute Medicine – also open to trainees from diverse backgrounds, this course is in its 8th year

Procedure and Communication Course in Intensive care – a new component with simulations and role plays

Australasian ICM Clinical Refresher Course – now in its 15th year, with over 500 attendees over this time.

USEFUL CONCEPTS FROM OTHER DISCIPLINES

EDUCATIONAL THEORY

Much has been written about adult learning theories. Arguably, the best known is from David Kolb. In the early 1970s he concluded that the way people learn is linked to how they *perceive an experience*. The Kolb learning cycle differentiates steps in learning including experiencing, reflecting, thinking and doing. The Kolb Learning Style Inventory has been available for many years and has been used by all disciplines, including health care.[13]

The lesser-known VARK learning style classification is based on systematic differences in how learners prefer to take in and put out information during learning experiences. VARK is an acronym for Visual, Aural, Read/Write and Kinesthetic (concrete experiences).[14]

Such classification tools may offer exam candidates insights into their own most- and least-preferred styles and assist personal preparation. For example, visual

Box 14.4 Mind maps™

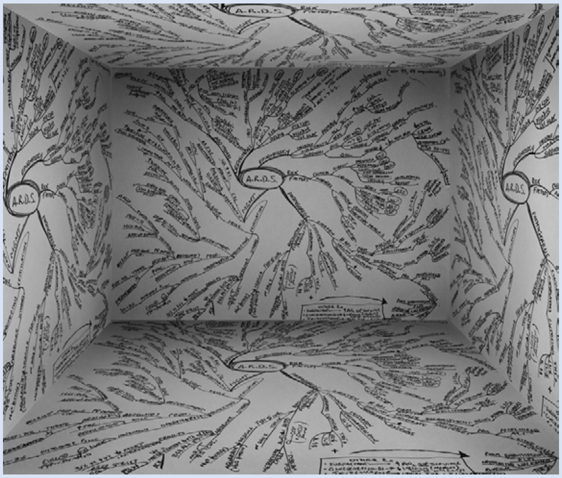

Figure 14.1 'Original mind map'. *(ARDS by Dr Niall Kennedy, Intensive Care Senior Registrar, Sydney. Image courtesy of Matt Tinker photography www.matthewtinker.com.au.)*

Tony Buzan is arguably the modern father of this technique and the term *mind map* is a trademark of his company.

They are used to summarise and link concepts and key terms diagrammatically to facilitate understanding and recall.

Buzan centres. Online. Available: http://www.buzan.com.au/learning/mind_mapping.html.

learners may benefit from utilising techniques such as mind-maps™ (**Box 14.4**) to prepare study notes compared with read/write learners who prefer to make lists and summaries on cards. Non-kinesthetic individuals who prefer reflection and thinking may find learning through simulations difficult and similarly may anticipate the need to work harder to establish comfort with examinations utilising role-plays and manikin-based simulations. Although these assumptions are rational, there are, however, no data supporting the theory that trainees would benefit from formally profiling their learning styles.

SPORTS PSYCHOLOGY

Some trainees, particularly those who have significant performance anxiety or have experienced failure, may benefit from methods used by high-performance athletes. Sports psychology techniques including cognitive behavioural therapy may aid successful performance and hence success. Some critical care trainees have been effectively coached by a performance psychologist (**Box 14.5**) as a major component of their exam preparation.

Box 14.5 Performance psychology for doctors in action

I have been working for many years with hospital registrars to assist with exam preparation, particularly after experiencing failure. This involves looking closely at their lifestyle, family commitments, specific exam requirements, work rosters, overtraining issues, specifics of previous failures and study patterns. It is enormously rewarding.

For the trainee who has failed previously, the immediate reaction is to work harder rather than smarter. Restructuring the study process can break the cycle of frustration and stress after failure. For example, the most opportune time to do creative and productive work is up to midday, as the body reaches maximum activation levels then.[15] So it is suggested that much of the reading and memorizing of material take place on mornings of work-free days. Also important is the daily self-testing on work under timed exam conditions to provide written and oral feedback to the trainee.

Trainees who monitor their study and receive regular feedback are more likely to remain focused on their study goals.[16]

ICM exams are structured in a manner that tests the accuracy of responses under tight time, pressured conditions. It is suggested that sample questions are practised under less than the permitted time per question, in order for the trainee to become accustomed to writing and thinking under pressure. Through overlearning and practice this repetitious behaviour becomes habitual. Compared with non-habitual behaviours, these habits require less conscious attention and effort, and can be performed faster.[17,18]

Issues such as poor oral delivery, low self-esteem, high anxiety, poor motivation, lack of confidence and/or assertiveness can be addressed through the use of goal setting, cognitive restructuring, arousal regulation and imagery. For instance, arousal can mediate attentional focus so that activities that are easy to perform in a stress-free environment become substantially more difficult in a pressure-packed situation.[19] A centring breath can yield physical balance and allow a trainee to mentally focus before attempting a task.[20] Bringing a trainee's focus to the present and enhancing body awareness is a foundation of mindfulness training.[21] Rather than reacting to perceived stressors as if on autopilot, the trainee focuses on breathing and bringing awareness to the inhalation and exhalation of the breath. This is especially useful before oral responses.

Through daily self-monitoring with regular use of a digital voice recorder, a timer, and a diary to record scores for imagery, arousal regulation, effectiveness of study focus, and oral or written feedback, there is a likelihood of better exam results. Trainees report that they feel more in control before exams and they are more likely to experience success.

Dr Patsy Tremayne, Adjunct Associate Professor at the University of Western Sydney, and foundation member of the Australian Psychological Society's College of Sport and Exercise Psychologists (CoSEP).

CONCLUSION

The challenge of examination processes is to help ensure trainees are prepared for the *real world* of specialist practice. It is overly simplistic to think that single examinations will achieve this alone. Comprehensive, quality, patient-centred training programmes, with regulatory bodies with clear governance structures that employ a combination of summative and formative assessment, are likely to achieve closer to the mark.

Overview of shock

Matthew J Maiden and Sandra L Peake

DEFINITION

The answer commonly provided to the question 'what is shock?' is often a vague 'patient with a low blood pressure', followed by some threshold blood pressure below which 'shock' is said to be occurring.

The reason for the uncertainty about what should be a simple concept relates to the fact that the term 'shock' is used in a multitude of contexts (e.g. septic, haemorrhagic, distributive, hypovolaemic, cytotoxic, cardiogenic, anaphylactic, toxic, spinal, neurogenic, cervical and, even electrical shock). However, the unifying feature of shock, irrespective of the initiating disease or clinical features, is *a failure to deliver and/or utilise adequate amounts of oxygen*.[1]

A thorough understanding of what constitutes shock is essential for all critical care practitioners. This chapter will outline the pathophysiology of shock, a classification of diseases that lead to shock and an approach to management.

CIRCULATORY PHYSIOLOGY

OXYGEN DELIVERY

Each day the heart pumps 8000 litres of blood deliver O_2 and nutrients to an estimated 100 trillion cells. This circulatory supply of O_2 and nutrients is tightly regulated by the cardiovascular system. Oxygen delivery (D_{O_2}) is the product of cardiac output (CO) and the oxygen content of arterial blood. D_{O_2} (mL/min) can be summarised by the following equation:

$$D_{O_2} = CO \times ([1.39 \times Hb \times Sa_{O_2}] + [Pa_{O_2} \times 0.003]) \qquad (15.1)$$

where Hb is the haemoglobin concentration (g/L), Sa_{O_2} is the arterial Hb saturation and Pa_{O_2} is the arterial oxygen partial pressure. The exact value of the haemoglobin O_2-carrying capacity constant is variably listed as either 1.34 mL O_2/g Hb (directly measured) or 1.39 mL O_2/g Hb (theoretical maximum O_2-carrying capacity).

Assuming adequate arterial oxygen content, CO is the main determinant of D_{O_2}. CO, in turn, is the product of heart rate (HR) and stroke volume (SV) with preload, afterload and myocardial contractility determining SV. Thus:

$$CO = HR \times SV\,(\text{preload}, \text{afterload}, \text{contractility}) \qquad (15.2)$$

Alterations in any of these determinants of CO will eventually lead to the development of different 'types' of circulatory shock (e.g. hypovolaemic, distributive, cardiogenic).

D_{O_2}–V_{O_2} RELATIONSHIP

Global D_{O_2} in the adult at rest is approximately 1000 mL/min and oxygen consumption (V_{O_2}) is about 250 mL/min. Under normal circumstances, the extra O_2 being supplied is not required to meet metabolic demand and can conceptually be thought of as a reserve supply (O_2 supply independency). In healthy volunteers at rest, D_{O_2} can be decreased from 14 mL/kg/min to 7 mL/kg/min without signs of inadequate oxygenation.[2]

If D_{O_2} decreases, V_{O_2} initially remains unchanged as the reserve O_2 is utilised. If D_{O_2} falls further, oxygen extraction from Hb is increased to maintain adequate oxygen supply to the tissues. Once O_2 is maximally extracted from Hb, any further reduction of D_{O_2} will limit O_2 supply (O_2 supply dependency). (**Fig. 15.1**).

DYSOXIA

Dysoxia occurs beyond the critical point of supply dependency (critical D_{O_2}). Inadequate O_2 supply leads to anaerobic cellular metabolism, less efficient adenosine triphosphate (ATP) production and consequent cellular and organ dysfunction. Clinically, the expression of dysoxia-induced cellular dysfunction is manifested by features of impaired end-organ perfusion such as drowsiness, delayed capillary refill, oliguria and hyperlactataemia. If the process leading to shock is identified and managed early and appropriately, cellular dysfunction is limited. However if dysoxia persists, the ongoing limitation of O_2 supply affects cell membrane ion channels, leading to an influx of sodium and water, cellular oedema, breaching of cell membrane integrity, cell injury and eventually, cell death.

The ability to withstand limited O_2 supply varies between organs. The heart and brain have high metabolic requirements with a relatively high oxygen extraction, and hence are more vulnerable to reduced O_2 supply. In contrast, the kidney and skin have relatively lower metabolic requirements and lower O_2 extraction and, therefore, are more tolerant of decreased D_{O_2}. The critical D_{O_2} also varies between individuals and is affected by metabolic demand, age, gender, co-morbid diseases, underlying organ function and medications.

Importantly, dysoxia may also occur despite adequate D_{O_2}. In conditions such as sepsis and multi-organ dysfunction syndrome, global D_{O_2} can appear to be adequate and may even be supranormal as a result of increased CO. However, arteriolar shunting around the microvascular beds prevents O_2 delivery to the cells and inflammatory mediators can induce mitochondrial dysfunction, preventing cells from utilising available O_2 (cytotoxic shock).[3–5] Hence *hypotension is not required to define 'shock'*.

'TYPES' OF SHOCK

Clinically, the impairment of circulatory supply of O_2 to the cells is commonly classified according to which component of the circulation is primarily disturbed – that is, hypovolaemic shock (inadequate preload), cardiogenic shock ('pump' failure), obstructive shock (obstructed pump outflow), and distributive or vasodilatory shock (altered vascular capacitance). The classification of shock into various types is clinically useful as it has therapeutic implications; albeit this distinction is sometimes too simplistic. For example, in septic shock, hypovolaemia (decreased preload secondary to increased vascular permeability), vasodilation and myocardial dysfunction may all coexist.

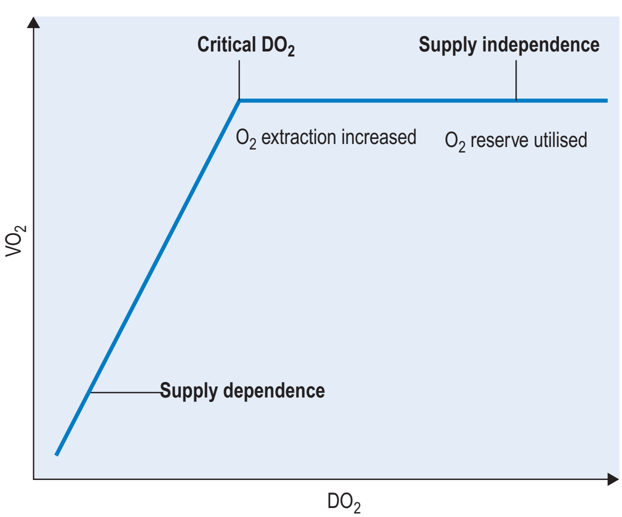

Figure 15.1 Oxygen supply and demand relationship.

HYPOVOLAEMIC SHOCK

Total blood volume is 70 mL/kg and comprises blood cells and serum. Hypovolaemic shock occurs when acute blood loss or excessive fluid losses (e.g. gastrointestinal, urinary tract, burns) lead to decreased circulating blood volume (**Box 15.1**).

Loss of circulatory volume will reduce preload and SV. About 10% of circulating volume loss can be restored by the movement of interstitial fluid into the circulation. Blood loss beyond this invokes cardiovascular compensatory mechanisms in order to restore preload and maintain CO and systemic blood pressure. These mechanisms include:

- *Increasing venous tone:* venoconstriction is an early compensatory response to hypovolaemic shock. The venous system holds about 80% of blood volume and acts as a blood reservoir. The sympathetic nervous system controls venous tone and capacitance of the venous system. Reducing capacitance favours venous return to the heart in an attempt to maintain SV.
- *Increasing arteriolar tone:* sympathetic stimulation of arteriolar resistance vessels increases perfusion pressure to the organs. However, this does not necessarily equate with increased blood flow. The extent of change of arteriolar tone varies between organs in order to ensure adequate blood flow to the vital organs.
- *Increasing HR:* to compensate for the reduction in SV, HR is increased in an attempt to maintain CO.

Box 15.1 Causes of hypovolaemic shock

Blood loss
Vascular injury (e.g. trauma, surgery)
Gastrointestinal bleeding (e.g. peptic ulcer, diverticular, angio-dysplasia, varices)
Obstetric bleeding (e.g. placenta praevia, post-partum haemorrhage)
Intra-abdominal haemorrhage (e.g. splenic laceration, liver injury)
Retroperitoneal (e.g. aortic aneurysm, ectopic rupture, femoral artery bleeding, pelvic fracture)
Long-bone fracture
Pulmonary haemorrhage, haemothorax

Fluid loss
Vomiting
Diarrhoea
Ileostomy losses
Sweating
Polyuria (e.g. glucosuria, diabetes insipidus)
Burns
Pancreatitis
Ascites

Inadequate fluid intake

- *Increasing contractility:* the heart will contract more vigorously in order to increase SV and maintain CO.

The American College of Surgeons classified the severity of haemorrhagic shock according to the presence of certain clinical signs (**Box 15.2**).[6] However, these 'classes' are arbitrary and depend on the rate of blood loss and factors that modulate the critical D_{O_2} (e.g. co-morbidities, medications).

Priorities in the management of hypovolaemic shock are: (1) controlling the source of blood and/or volume loss, and (2) restoring the circulating volume.

CARDIOGENIC SHOCK

The heart is central to the circulatory supply of O_2 and if the pump fails then there are few compensatory mechanisms available. Hence, cardiogenic shock has a very high in-hospital mortality rate ranging from 45–100%, depending on the aetiology.[7] Myocardial ischaemia is the most common cause of cardiogenic shock, but other aetiologies must be considered (**Box 15.3**).

Treatment priorities in cardiogenic shock involve urgent correction of the underlying acute cardiac disease and consideration of afterload reduction while ensuring adequate organ perfusion.

OBSTRUCTIVE SHOCK

Mechanical obstruction to the flow of blood through the cardiac chambers will lead to reduced cardiac output. The limitation of flow may be due to obstruction within the heart (e.g. valve thrombosis, myxoma) or extrinsic compression (e.g. tension pneumothorax, cardiac tamponade). Treatment is directed at urgent removal of the obstruction (e.g. drainage of pericardial effusion, lysis of thromboembolism).

DISTRIBUTIVE SHOCK

Blood distribution around the vascular network is controlled by vascular autoregulation, the autonomic nervous system and hormones. Distributive shock results from the failure of these mechanisms, leading to inappropriate distribution of blood (**Box 15.4**). Unlike other forms of shock, CO may initially be increased as the heart endeavours to compensate for maldistribution of blood.

Management priorities are to identify and treat the precipitating cause and to improve organ perfusion with resuscitation fluids and vasoactive drugs. Sepsis is the most common cause of distributive shock in the ICU and prompt resuscitation of the circulation is essential for improved survival.

CLINICAL SIGNS

The clinical features of shock relate to a critically inadequate circulation and insufficient O_2 delivery and/or utilisation. However, these features are non-specific and will depend on a number of factors including:

- process leading to shock
- severity of precipitating disease or injury
- physiological reserve of the patient
- effects of medications.

The compensatory mechanisms to shock and subsequent clinical manifestations are affected by advancing

Box 15.2 Classes of haemorrhagic shock (American College of Surgeons 2004)

Class 1
<15% blood volume loss
Compensated by shift of interstitial fluid
Minimal clinical changes

Class 2
15–30% blood volume loss
Compensated hypovolaemia
Features include orthostatic hypotension and tachycardia

Class 3
30–40% blood volume loss
Decompensated hypovolaemia
Hypotension, tachypnoea, altered mental state

Modified from American College of Surgeons. Committee on Trauma. ATLS, advanced trauma life support program for doctors. 7th ed. Chicago, IL: American College of Surgeons; 2004.

Box 15.3 Causes of cardiogenic shock

Myocardial ischaemia
Acute valve dysfunction (e.g. chordae rupture, prosthetic valve thrombus)
Myocarditis
Contusion
Septal/ventricular rupture
Drugs (e.g. Ca^{2+} channel blocker overdose, beta blocker overdose)
Bradyarrhythmias (e.g. complete heart block)
Tachyarrhythmias (e.g. atrial or ventricular tachycardias)

Box 15.4 Causes of distributive shock

Septic shock
Toxic shock
Anaphylactic shock
Neurogenic shock
Adrenal/thyroid insufficiency
Toxicity (e.g. drugs)
As a component of multi-organ dysfunction syndrome

age, cardiovascular disease, autonomic disease and medications. For example, patients on beta antagonists will not mount the same tachycardic response to fluid loss and patients with pre-existing cardiac disease are less capable of circulatory compensation and so develop features of shock earlier.

Due to the non-specific and varied clinical signs of shock, repeated assessment with frequent monitoring of vital signs is essential.

Hypotension is a sentinel feature of shock and signifies circulatory failure. However, hypotension develops late as systemic blood pressure is initially maintained by compensatory mechanisms (i.e. vasoconstriction, tachycardia, increased myocardial contractility).

A decline in mean arterial pressure (MAP) below the lower limit of autoregulation results in reduced perfusion to the vital organs. In a healthy adult, tissue perfusion is typically impaired with a MAP of ≤50 mmHg (6.65 kPa). In contrast, elderly patients with pre-existing hypertension or vascular disease generally require a higher MAP to ensure adequate regional blood flow.

If systemic blood pressure cannot be accurately determined by the usual auscultatory techniques, then the patient is likely to be markedly hypotensive. Establish the presence of a central (carotid, femoral) or peripheral (radial, posterior tibial) pulse, followed by palpation of the systolic blood pressure using a blood pressure cuff.

Tachycardia is an early compensatory sign of shock. However, in some conditions bradycardia is the cause of shock (e.g. complete heart block, increased vagal tone in cervical shock, unopposed vagal tone in neurogenic shock).

Tachypnoea steadily increases with worsening shock but falls in the pre-terminal phase of shock.

Oliguria is secondary to reduced glomerular filtration and increased filtrate reabsorption. In shock states, the rate of urine production is a useful guide to adequacy of the circulation.

Altered mental status is a common feature of shock as cerebral function is very sensitive to altered O_2 delivery. During shock, mental state progressively changes from anxiety, agitation, confusion and delirium, toward drowsiness and coma.

Impaired peripheral perfusion provides a clinically useful clue regarding the likely mechanism of shock. Cool, clammy peripheries with pale or mottled skin are suggestive of hypovolaemic or cardiogenic shock, whereas warm peripheries are suggestive of distributive shock.

MANAGEMENT

Resuscitation of shock is a medical emergency. The aim of therapy is to rapidly and effectively restore systemic D_{O_2} and improve tissue perfusion. History, examination and investigation (**Box 15.5**) must occur concurrently with resuscitation. The usual resuscitation principles of airway, breathing, circulation apply.

The principles of management of shock are:

1. Supply O_2
2. Vascular access
3. Volume resuscitation
4. Vasoactive agents
5. Manage precipitating illness or injury
6. Monitoring.

1. Supply oxygen

Ensure any causes of hypoxia are urgently corrected including providing adequate Fi_{O_2}, ensuring ventilation is adequate and that any reversible cause of pulmonary shunt is corrected (e.g. pleural collection, bronchus obstruction).

2. Vascular access

Insertion of intravenous cannulae is essential for administration of fluids and medications. Cannula size is an important consideration as it has major implications for the rate of laminar fluid flow. Poiseuille's law describes the variables contributing to laminar flow rates:

$$Q \propto (\Delta P \times \pi r^4) / (8 \times \text{viscosity} \times \text{length}) \qquad (15.3)$$

This emphasises the dramatic effect of radius on flow and that flow is inversely proportional to cannula length. Hence for rapid intravenous fluid administration, venous cannulation using short wide-bore catheters is essential.

Flow rates achieved through different diameter intravenous cannulae are stated to range from 44 mL/

Box 15.5 Investigations for shock (as clinically indicated)

Bedside
Haemoglobin
Arterial blood gas
Lactate
ECG
Ultrasound (e.g. FAST scan, AAA scan)
Echocardiogram

Laboratory
Full blood count, coagulation studies, D-dimer
Electrolytes, creatinine, urea, liver function tests
Cardiac enzymes, lipase

Toxicology assays

Radiology
Chest, abdominal X-ray
Trauma series radiology (chest, pelvis, C-spine)
CT
Angiography (e.g. coronary, visceral, pulmonary)

min (22 G; 0.9 mm diameter) through to 286 mL/min (14 G; 2.1 mm diameter). However, as flow through cannulae is turbulent rather than laminar, flow rates are lower than those quoted.[8]

3. Fluid resuscitation

Fluid resuscitation is usually the first therapeutic strategy in the management of shock, particularly in hypovolaemic or distributive shock. However, it is important to note that not all patients will respond to fluid loading with a significant increase in CO. If the heart is working on the terminal (flat) portion of the Frank–Starling curve, increased preload may not result in a significant increase in SV. Nevertheless, even patients with cardiogenic shock may benefit from a judicious fluid challenge and dynamic assessment of volume responsiveness (i.e. the ability to increase CO with fluid loading or straight leg raise) is preferred to static measurements of volume state (e.g. central venous pressure).

Trendelenburg A quick method to increase venous return is to tilt the patient's pelvis above horizontal (i.e. head down). This will 'auto-transfuse' blood from leg and pelvic veins and increases venous filling pressures and MAP. Increases in CO are minimal if venous capacitance remains high and the extra blood volume is accommodated.

Crystalloids Crystalloid solutions comprise electrolytes (with or without dextrose) and water. These fluids cross semipermeable membranes easily and are rapidly distributed through the intravascular and extravascular spaces. The time for fluid equilibration across the body compartments depends on: (1) osmolality of the fluid, (2) solute clearance and (3) integrity of the vascular endothelium.

Although the choice of fluid should reflect the composition of the fluid lost, 0.9% saline is commonly used for initial volume replacement. 0.9% saline is slightly hyperosmolar (300 mOsm/L) and hyperchloraemic (150 mEq/L) relative to plasma. When large volumes are used for resuscitation, hyperchloraemia can contribute to bicarbonate loss and a normal anion gap metabolic acidosis. Lactated Ringer's solution (Hartmann's) is isotonic and contains lactate (29 mEq/L) and electrolytes in a ratio similar to plasma. However, the calcium in Hartmann's (4 mEq/L) is incompatible with certain drugs and lactate levels may rise if hepatic function is markedly impaired or a lot of fluid is administered. Other crystalloid solutions are available that contain different buffer anions and slightly different composition of electrolytes. These have not been shown to alter clinical outcomes following fluid resuscitation.

Concentrated saline is theoretically a useful resuscitation fluid since a small volume can increase circulating volume (e.g. 250 mL 7.5% saline can increase circulating volume by 500 mL). However, the sodium also passes into interstitial space leading to increased interstitial fluid volume, at the expense of intracellular volume. Volume resuscitation with hypertonic saline may prevent cerebral oedema, but a recent clinical trial of its use in head-injured patients did not show improved outcomes.[9]

Colloids Colloids are solutions containing large molecules that do not pass through a semipermeable membrane. These solutions remain in the circulation for longer, have a smaller volume of distribution and hence are more effective at increasing intravascular volume than the same volume of crystalloid. There are a number of colloid solutions available, which differ based on their type and concentration of colloidal molecules.

Albumin Four per cent normal serum albumin (NSA 40g/L; 260 mOsm/L) is iso-oncotic and infusion rapidly increases circulating volume. NSA is a by-product of whole blood separation; however, it is provided in glass bottles that limit the speed of infusion and the increment in plasma volume lasts only a few hours.[10] Concentrated (20%) albumin is available in smaller volumes (100 mL). It increases circulating fluid volume by drawing fluid from the interstitium. This process takes time and concentrated albumin is not a useful resuscitation fluid.

Whether crystalloid or colloid solution is the better resuscitation fluid is a matter of much debate. Crystalloids are cheap, easy to administer and replete intravascular and extravascular fluid. Their tendency to interstitial oedema and electrolyte alteration is thought to be a problem. Colloids can restore circulating volume more quickly, persist for longer (at least initially) and seem less likely to lead to interstitial oedema. However colloids are more expensive, have a greater risk of side-effects and in critically ill patients can accumulate in the interstitium, contributing to persistent interstitial oedema.

In 1998, a Cochrane review suggested albumin use was associated with increased mortality,[11] but other reviews drew different conclusions.[12–14] To determine the safety of albumin as a resuscitation fluid, the Saline versus Albumin Fluid Evaluation (SAFE) study randomised 7000 patients to receive albumin or crystalloid as their resuscitation fluid.[15] This landmark study revealed that patients receiving albumin required less intravenous fluid, but clinical outcomes were no different to patients who received saline resuscitation. Subgroup analyses suggested that septic patients fared better with 4% NSA, while head-injured patients given saline had better outcomes.

Starch Solutions Starch solutions contain a carbohydrate polymer (starch) as their oncotic molecule and differ according to the type and molecular size of the starch used (high starch 450 000 D, medium starch 200 000 D, low starch 70 000 D). The starch polymers undergo degradation by serum amylase with the fragments cleared by the kidney. The duration of oncotic

effect is related to the size of the starch molecule and clearance rates. Whereas starch solutions provide effective intravascular volume replacement and are convenient to administer, their use in patients with septic shock has been associated with increased risk of death, renal impairment and bleeding risk.[16,17] A recent clinical trial of 7000 ICU patients randomised to receive 6% hydroxyethyl starch (HES; 130/0.4) or 0.9% saline as resuscitation fluid found no difference in mortality, but patients who received 6% HES had an increased need for renal replacement therapy and a greater incidence of skin reactions.[18]

Blood The use of blood is essentially limited to shock from acute blood loss or for correcting anaemia that may be contributing to impaired O_2 delivery.

4. Vasoactive agents

When fluid administration alone fails to restore adequate oxygen delivery and organ perfusion, vasoactive agents should be initiated. In extreme shock, it may be necessary to commence fluid resuscitation and vasoactive therapy concurrently.

Vasoactive agents are commonly referred to as 'inotropes' as many of them increase cardiac contractility (i.e. inotropy). However, many agents have their primary effect on vascular tone rather than directly altering contractility. The choice of agent will depend on which aspect of the cardiovascular physiology is deranged and the goals of therapy.

For cardiogenic shock, medications may be required to increase contractility (e.g. dobutamine, milrinone, levosimendan), reduce afterload, maintain adequate systemic and coronary perfusion pressure, increase diastolic relaxation and increase or decrease heart rate. In distributive shock, medications that produce venoconstriction and increased systemic pressures are required. There is little role for cardiovascular medications in hypovolaemic shock; however, the effect of vasopressin is currently being investigated in a prehospital clinical trial.[19]

The choice of which catecholamine to use in shock (i.e. norepinephrine (noradrenaline) vs epinephrine (adrenaline) vs dopamine) has been the subject of considerable debate and opinion. Different catecholamines exhibit different pharmacological properties (e.g. β_1- vs β_2 adrenergic receptor stimulation); however, the superiority of one catecholamine over another has not been demonstrated in any large-scale clinical trials. A large randomised trial of patients with shock reported no difference in 28-day mortality between norepinephrine and dopamine,[20] while an Australian trial found no difference between norepinephrine and epinephrine in patients with shock from any cause.[21] Similarly in septic shock, there is no mortality difference if using epinephrine or norepinephrine with dobutamine.[22] It is not surprising that there is no one 'ideal' vasoactive agent for every patient or for all causes of circulatory shock. Instead these drugs should be chosen based on the desired therapeutic effects on the cardiovascular system.

Although blood pressure is a universal measure of circulation adequacy and often a therapeutic target when using vasoactive agents, there are no randomised controlled trials evaluating the ideal MAP. Choice of ideal MAP remains empirical and is based on the clinician's assessment of the minimum pressure thought to represent adequate blood flow taking into consideration pre-existing comorbidities such as hypertension or vascular disease.

Augmenting the circulation with vasoactive agents to provide 'supranormal' D_{O_2} was previously thought to be a therapeutic option for critically ill patients. However, several clinical trials have repeatedly illustrated that efforts to drive D_{O_2} beyond normal do not improve survival.[23–25]

5. Manage precipitating illness or injury

As the circulation is being resuscitated, the cause of the circulatory disturbance needs to be identified and corrected. Unless this occurs, shock will continue to worsen and death will ensue. Time to definitive treatment of the cause of shock is related to survival. This has been clearly illustrated in cardiogenic shock (time to reperfusion),[26] haemorrhagic shock (time to haemorrhage control)[27] and septic shock (time to appropriate antibiotics).[28]

6. Monitoring

All causes of shock have improved outcomes when managed in an environment that closely monitors clinical signs and physiological parameters (i.e. an ICU).

Clinical monitoring involves frequent assessment of heart rate, blood pressure, respiratory rate, conscious state, urine output, peripheral perfusion and temperature.

An arterial cannula provides beat-to-beat measurement of systemic pressure and is particularly useful for measuring blood pressure when clinical techniques become difficult and unreliable. Arterial cannulae also allow ready sampling for blood gas and lactate measurement.

A central venous cannula allows measurement of central venous pressure (CVP), which is often used as an estimate of venous volume, and hence preload. However, CVP bears a variable relationship to venous volume, as it is dependent on location of the catheter to the right atrium, intrathoracic pressures, venous compliance, position of the patient and tricuspid valve competence. Thus CVP is a guide to the *pressure* status of the venous system rather than a measure of intravascular volume and preload. CVP correlates poorly with fluid response to shock.[29]

Echocardiographic assessment of end-diastolic ventricle volume may better a predictor of preload than invasive pressure measurement, but the technique is operator- and patient-dependent.

As there is no 'gold standard' measure of preload, any monitored variable assessing volume state should

be interpreted in conjunction with clinical findings. Repeated assessment and dynamic measures such as systolic pressure variation (in ventilated patients) and response to fluid challenge (e.g. fluid bolus or straight leg raise) are a more useful guide to preload adequacy than static measurements.[30,31]

Some CVCs contain an oximeter in the tip that measures O_2–Hb saturation of central venous blood (Scv_{O_2}). This can be used as a guide to determine O_2 demand and adequacy of D_{O_2}, and to help direct further resuscitation. An $Scv_{O_2} \geq 70\%$ has been proposed as a resuscitation goal.[32] However, Scv_{O_2} is a general measure of global O_2 demand, does not measure the impact of coronary venous blood (from the coronary sinus) and inadequate D_{O_2} may still occur despite a normal or high Scv_{O_2} (viz. anatomical shunts, microcirculation shunting).

Measuring CO in patients with shock is not required routinely. In most patients, clinical assessment provides adequate information regarding CO. There is no evidence that targeting therapy to a specific CO improves outcomes. However, measurement and monitoring may be necessary if a patient's circulatory disturbance does not improve following initial treatment. There is an ever-increasing number of techniques available for estimating CO, all with inherent strengths and limitations. Further discussion of haemodynamic monitoring is found in Chapter 16.

Blood gas, pH and lactate monitoring provide some guidance to the adequacy of cellular resuscitation.[32,33] Inadequate oxygen delivery and/or utilisation is the most common cause of elevated serum lactate (generally defined as >2 mmol/L) in ICU patients. Blood lactate levels, lactate clearance rates and falling base deficit are associated with poor outcomes[34–37] and are a better predictor of mortality than is D_{O_2} or V_{O_2}.[38] However, lactate is not specific for shock, as elevated levels may also occur with liver failure (reduced lactate metabolism), thiamine deficiency (inhibits pyruvate dehydrogenase), lactate administration (e.g. in dialysis fluids), catecholamine administration (beta agonists) and prolonged exercise. Elevated blood lactate levels may also reflect regional dysoxia of an isolated anatomical organ or tissue (e.g. limb or bowel ischaemia) that may not necessarily be associated with a global circulatory disturbance. The role of targeting therapies to lactate clearance or base excess also remains uncertain.

Standard ICU monitoring techniques focus on assessment of the macrocirculation. However, there is growing interest in how the microcirculation can be monitored. Microscopic analysis of the circulation with orthogonal polarisation spectral (OPS) imaging or near infra-red spectroscopy (NIRS) provide fascinating insights into the microcirculatory status, but their use remains experimental.

Haemodynamic monitoring

David J Sturgess

INTRODUCTION

Haemodynamics is the study of blood flow. Haemodynamic monitoring therefore refers to the monitoring of blood flow through the cardiovascular system. In critical care, including the intensive care unit (ICU), haemodynamic monitoring is used to detect cardiovascular insufficiency, differentiate contributing factors, and guide therapy.

There has been debate over the risks and benefits of invasive haemodynamic monitoring in critically ill patients. In the presence of scant data demonstrating an association between invasive monitoring and improved survival, there has been a steady trend toward less invasive monitoring in the ICU.

At the bedside the clinician must work with inexact surrogates of preload, contractility and afterload, measured or derived from arterial blood pressure (systemic or pulmonary), volume or pressure indices of cardiac filling, stroke volume or cardiac output, and various markers of tissue well-being. As a rough guide to the layout of this chapter, clinical observation and evaluation will be considered briefly before progressing to monitoring that is primarily concerned with the measurement of pressures (including catheterisation, equipment and techniques) then flow (cardiac output). The concept of functional haemodynamic monitoring, including the prediction of fluid responsiveness, will be introduced, along with perioperative optimisation. Finally, monitoring of perfusion in the microcirculation will be briefly mentioned.

CLINICAL OBSERVATION AND EVALUATION

The diagnosis of haemodynamic disturbance requires combination and integration of available data.[1] This should include physical examination and review of observations such as pulse, peripheral perfusion (capillary refill and temperature), oedema, urine output, oxygen saturation and end-tidal carbon dioxide.

Electrocardiographic (ECG) monitoring is almost universally indicated in the intensive care unit. Generally a system requiring a reduced number (<10) of electrodes is used. This has benefits in terms of patient comfort and convenience for caregivers. However, it must be kept in mind that when compared to the recorded 12-lead ECG, reconstructed 12-lead ECG data appear to retain specificity but can be significantly less sensitive across a range of rhythmic and morphological abnormalities.[2]

PRESSURE-BASED CARDIOVASCULAR MONITORING

This section will discuss monitoring that is primarily employed for monitoring pressure-based cardiovascular variables. Equipment, techniques and supplementary variables will also be discussed under the most applicable headings.

ARTERIAL BLOOD PRESSURE

The systemic pulse wave propagates from the aortic valve at 6–10 m/s. During its passage into the peripheral vasculature there is a progressive increase in systolic (SBP) and reduction in diastolic blood pressures (DBP), as standing and reflected waves become incorporated into the waveform, a process known as distal pulse amplification. Consequently, systemic arterial pressure measurements vary according to the site of measurement.

Mean arterial pressure (MAP) is arguably a more relevant index to monitor than either SBP or DBP for three reasons:

- MAP is least dependent on measurement site or technique (invasive versus non-invasive).
- MAP is least altered by measurement damping.
- MAP determines tissue blood flow via autoregulation (apart from the left ventricle, which autoregulates from diastolic pressure).

NON-INVASIVE ARTERIAL BLOOD PRESSURE MEASUREMENT

In critical care, most standard non-invasive arterial blood pressure (NIBP) instruments are automated intermittent oscillometric devices. Finger plethysmography and arterial tonometry can monitor both arterial pressure and waveforms continuously, but concerns exist regarding accuracy.

Oscillometric NIBP is often used to check the reliability of invasive measurements, or can be used alone when beat-to-beat monitoring is not required. Contraindications to NIBP are relative, and influence the site of cuff placement. For instance, it is preferable to avoid extremities with severe peripheral vascular disease, venous cannulation, arteriovenous fistula or a predisposition to lymphoedema, as may occur after lymph node clearance.

To make an oscillometric blood pressure measurement, a pneumatic cuff is inflated around a proximal limb until all oscillations in cuff pressure are extinguished. The occluding pressure is then lowered stepwise, so that oscillations reappear over a discrete interval. Proprietary algorithms compute mean, systolic and diastolic pressures from the alterations in oscillatory amplitude during deflation.

Oscillometry overestimates low pressures and underestimates high pressures, but for the normotensive range the 95% confidence limits are ±15 mmHg (2 kPa). Dysrhythmia increases the error. Cuff width should be 40% of the mid-circumference of the limb. Narrower cuffs overestimate and wider cuffs underestimate blood pressures.

Complications are unusual. Repeated cuff inflations can cause skin ulceration, oedema and bruising, more so when the consciousness is impaired by illness and sedation. Ulnar nerve injury is also possible, especially with low cuff placement.

INVASIVE BLOOD PRESSURE MEASUREMENT[3,4]

Invasive blood pressure measurement is desirable in the presence of haemodynamic instability, end-organ disease requiring beat-to-beat blood pressure monitoring, during therapeutic manipulation of the cardiovascular system or if non-invasive methods fail. Cannulation of a systemic artery allows continuous monitoring of the arterial pressure waveform, heart rate and blood pressure, and also facilitates frequent arterial blood gas analysis. Relative contraindications include coagulopathy and vascular abnormality or disease.

The radial artery is the most common site for cannulation; this preference has resulted from ease of cannulation, relatively consistent anatomy and low complication rates (incidence of permanent ischaemic complications ~ 0.09%). Nothing larger than a 20-gauge cannula is advisable, and either a modified Seldinger technique or direct cannulation can be used. Even though anatomical variation is common, adequate collateral flow exists in most patients. The modified Allen's test is sometimes employed prior to cannulation. Evidence is lacking regarding its ability to predict ischaemic complications during radial artery occlusion. Ultrasound (Doppler) might be a more reliable way of confirming collateral perfusion, as well as potentially improving cannulation rates with fewer attempts.

Once inserted, the cannula is usually infused with normal or heparinised saline at 3 mL/h, with a snap flush rate of 30–60 mL/h. The potential use of heparinised saline to prolong catheter patency must be balanced against the potential contamination of blood samples drawn through the cannula (especially APTT) and concerns regarding sensitisation and development of heparin-induced thrombosis thrombocytopenia syndrome (HITTS).

Caution must be used when using a functional end artery (e.g. brachial artery), as complications may manifest as a vascular emergency. In severe circulatory compromise, gaining peripheral arterial access may be difficult and time consuming. Rapid femoral cannulation by the Seldinger percutaneous technique usually remains feasible, with the added advantage that femoral arterial monitoring more accurately reflects aortic pressure in low-output states. This may be relevant in stroke volume estimates based upon arterial waveform characteristics.

No specific recommendations are made regarding planned resiting of cannulae.[5] In practice, cannulae are removed when no longer required, or resited when malfunctioning. This should be expedited if a complication is suspected. Distal perfusion should be checked at least 8-hourly, and the cannula removed if there is persistent blanching, coolness with sluggish capillary refill, loss of pulses, or evidence of raised muscle compartment pressures. Complications associated with arterial cannulation are presented in **Table 16.1**.

Physical properties of clinical pressure measurement systems[6]

In the standard setup, the arterial cannula is connected to a linearly responsive pressure transducer via fluid-filled non-compliant tubing <1 m in length. Modern disposable transducers are precalibrated using electrical signals, and are not normally calibrated further against known pressures. The system is zeroed to the level of the phlebostatic axis, normally the mid-axillary line at the fourth intercostal space. Subsequent lowering of the transducer relative to this axis will cause pressure overestimation, while raising it will cause underestimation.

The *natural resonant frequency* of the system should exceed 36 Hz (>10 harmonics with allowance for optimal damping which allows measurement of up to 67% of resonant frequency) for heart rates up to 180 beats/min (3 Hz), to prevent distortion of the biological signal by sine wave system oscillations. *Damping* refers to any property of an oscillatory system that reduces the amplitude of oscillations. Factors that increase oscillation in the system, such as increased tubing length, diameter or compliance, cause underdamping. Overdamping tends to smooth the waveform, causing underestimation of SBP and overestimation of DBP, while MAP tends to be preserved. Contributing factors include clots, air bubbles and loose connections.

Damping can be assessed clinically by the fast flush test. The fast flush or square wave test is performed by

Table 16.1 Complications of arterial cannulation, with suggested preventative and treatment option

COMPLICATION	PREVENTION	TREATMENT
Vascular thrombosis (ranges from 7–30% following radial artery cannulation). Risk factors for digital ischaemia include: shock, sepsis, embolus of air or clot, hyperlipoproteinaemia, vasculitis, female sex, prothrombotic states, accidental intra-arterial injection of drugs	Risks reduced by smaller catheter, larger artery, decreased duration of cannulation, avoiding traumatic insertion and multiple attempts. Allen's test (including modifications such as Doppler, plethysmography and digital blood pressure) is probably unhelpful	Remove cannula. Arterial thrombosis is usually self-limiting. Severe ischaemic damage estimated at <0.01%. Anticoagulation and/or vascular surgery/intervention may be necessary
Distal embolisation	Diligent catheter care and observation	As for thrombosis
Proximal embolisation of clot or air (can result in stroke)	Diligent catheter care and observation. Exclude air from pressurised system. Avoid axillary, subclavian, or carotid access	Tailored to sequelae
Vascular spasm	Smaller catheter, larger artery, Avoid traumatic insertion and multiple attempts	Remove cannula. Resite if necessary
Skin necrosis at catheter site	Diligent catheter care and observation	Surgical debridement and skin grafting may be necessary
Line disconnection and bleeding/ exsanguination	Minimise connections. Diligent catheter care and observation	Control bleeding. Transfusion may be necessary
Accidental drug injection	Clearly label arterial line near ports	Leave cannula in situ to facilitate treatment if required. Depends on drug injected. May require papaverine or procaine, analgesia, sympathetic block of limb and anticoagulation
Infection – local or systemic	Diligent catheter care and observation	Remove cannula and send tip for culture. Resite if necessary. Immobilise and elevate affected upper limb. Start empiric antibiotics if sepsis or septic shock is present
Damage to nearby structures such as nerves, directly or due to haematoma (e.g. compartment syndrome or carpal tunnel syndrome). Arteriovenous fistula. Femoral approach can be associated with bowel damage	Careful insertion technique. Seek assistance from experienced operator	Haematomas can develop into pseudoaneurysms requiring surgery

Source: Based on information contained in text of reference;[62] Durbin Jr CG. Radial arterial lines and sticks: what are the risks? Respir Care 2001;46(3):229–31.

opening the valve, thus transmitting the pressure from the pressure bag, of the continuous flush apparatus. This is then released/closed abruptly, inducing oscillation. With appropriate damping, the measured pressure should come to reflect the biologic signal within one or two oscillations.

Upstream resistance or turbulence can result in a flow-dependent pressure reduction at the cannula site that differs from damping in that the mean, systolic and diastolic pressures are all reduced. This is described as *attenuation* and is often observed in 'positional' arterial lines.

Estimation of stroke volume and cardiac output

Estimation of stroke volume by analysis of the arterial pressure waveform has been studied for many years. An array of algorithms has resulted, some of which have been incorporated into commercially available monitors. The underlying concepts are discussed further in the cardiac output monitoring section of this chapter.

CENTRAL VENOUS CATHETERISATION

Central venous catheterisation (CVC) is indicated for monitoring of central venous pressure (CVP). It may

also be required for administration of certain drugs and parenteral nutrition. In addition, it may be used as a component transpulmonary indicator dilution system for cardiac output monitoring. Modified catheters are also available which continuously monitor central venous oxygen saturation (Scv_{O_2}).

Contraindications to central venous catheterisation are relative and reflect potential complications of the procedure (**Table 16.2**). These should be considered in selecting the site for catheter insertion. The subclavian is preferred to internal jugular or femoral approaches with regarded to minimizing the

Table 16.2 Complications of central venous catheterisation, with preventative and treatment options

COMPLICATION	PREVENTION	TREATMENT
Intravascular loss of guidewire	Ensure guidewire is always secured. Avoid retracting guidewire into insertion needle. Seek assistance from experienced operator	Interventional radiology or surgery may be required for retrieval
Air embolism	Proper patient positioning, including Trendelenburg (head down tilt) for jugular or subclavian insertion. Consider alternative insertion sites. Ensure connections are tight	Left lateral Trendelenburg position. Administer 100% oxygen and ventilatory support. If catheter in place tighten all connections and attempt to aspirate air. Basic/ advanced life support if necessary
Dysrhythmias and conduction defects such as right bundle branch block	Continuous electrocardiographic monitoring during insertion. Correct placement of catheter tip	Withdraw or remove guidewire or catheter
Damage to nearby structures: Pneumothorax/haemothorax/ chylothorax/hydrothorax, particularly with approaches to subclavian vein. Nerve injury such as phrenic, recurrent laryngeal, Horner's syndrome. Arterial puncture – including injury to carotid, subclavian, aorta or pulmonary artery. Haematoma, pseudoaneurysm, arteriovenous fistula can result. Stroke may result from carotid artery injury. Tracheal injury. Femoral approach can be associated with bowel damage.	Identify risk factors such as previous surgery, skeletal deformity or scarring at site of insertion. Seek assistance from experienced operator. Select insertion site depending on impact of potential complications. Consider ultrasound guidance. Scheduled, routine replacement of catheter increases risk of mechanical complications	Depends on specific complication
Line disconnection and bleeding	Minimise connections. Proper catheter care and observation	Control bleeding. Transfusion may be necessary
Infection – local or systemic (including endocarditis)	Aseptic insertion technique. Lower risk with subclavian compared to internal jugular or femoral insertion. Antimicrobial impregnated catheters. Disinfect catheter hubs. Routine scheduled resiting appears not to reduce systemic infection rates. Remove catheter when no longer required	Remove catheter, resite if necessary. Culture blood and catheter tip. Start empiric antibiotics if sepsis or septic shock is present
Superior vena caval erosion can result in haemothorax or cardiac tamponade	Remove catheter when no longer required	Early detection and surgical intervention
Thrombosis	Remove catheter when no longer required. Subclavian insertion is lower risk than internal jugular or femoral	Anticoagulation, vascular or endovascular intervention may be required

Source: based on information contained in text of reference:[63] McGee DC, Gould MK. Preventing complications of central venous catheterization. N Engl J Med 2003;348(12):1123–33.

risk of central-line-associated bloodstream infections (CLABSI).[7] However, routine replacement of central lines does not appear to reduce CLABSI. Attention should also be given to the coagulation profile and factors that affect coagulation such as thrombolytic therapy.

Traditionally, puncture of the central vein is performed by passing a needle along the anticipated line of the vein with reference to surface anatomical landmarks (landmark method). Catheterisation is usually achieved via the subclavian, internal jugular or external jugular veins into the superior vena cava.[8] Access to the subclavian vein is usually via the infraclavicular approach, but the supraclavicular approach is safe and reliable in experienced hands. Peripherally inserted central catheters (PICC) are inserted via a peripheral vein, such as the cephalic or basilic vein and advanced until the tip lies in a central position.

In the United Kingdom, the National Institute for Health and Clinical Excellence (NICE) has issued guidelines recommending the use of ultrasound for elective catheterisation of the internal jugular vein, and consideration of ultrasound guidance in most clinical situations (formulated 2002, reviewed 2005).[9]

Ultrasound can be used to assist central line placement in a number of ways. Two-dimensional imaging with ultrasound can be used to localise the vein and define anatomy prior to placement of a CVC by standard landmark techniques. Ultrasound can also provide real-time, two-dimensional guidance during CVC insertion. Audio-guided Doppler ultrasound can also aid localisation of the vein and differentiate it from its companion artery during CVC insertion.

For catheters inserted via veins draining to the superior vena cava, the right tracheobronchial angle and carina are common radiological markers of insertion depth. In an attempt to further reduce the incidence of venous erosion (which is rare but potentially catastrophic), some practitioners place the catheter tip lower in the superior vena cava or even in the upper right atrium, ensuring that the catheter is parallel to the long axis of the vein so that the tip does not abut the vein or heart wall end-on.[10]

Many patients with chronic illness, such as malignancy, require long-term central venous catheterization (including PICC). Complications such as central line-associated bloodstream infection and thrombosis (concomitant risk of catheter infection, pulmonary embolus and post-thrombotic syndrome) may require ICU admission and management. Management of such complications is described in **Table 16.2**. In the setting of thrombosis, immediate removal is not necessarily advised.[11]

CENTRAL VENOUS PRESSURE

Jugular venous pressure, CVP and right atrial pressure (RAP) are often used interchangeably. However, in situations associated with increased central venous resistance, such as central vein sclerosis, these pressures may not be the same.

CVP is usually monitored using a fluid-filled pressure transduction system similar to that employed to measure invasive arterial pressures. Waveform analysis is also possible (**Table 16.3**). The normal CVP in the spontaneously breathing supine patient is 0–5 mmHg (0–0.65 kPa), while 10 mmHg (1.3 kPa) is generally accepted as the upper limit during mechanical ventilation. In health there is a good correlation between CVP and pulmonary artery occlusion pressures (PAOP), but this is lost in many types of critical illness such as pulmonary hypertension, pulmonary embolism, right ventricular infarction, left ventricular hypertrophy and myocardial ischaemia. The relationship between CVP and right ventricular end-diastolic volume (preload) is altered in critical illness by changes in right ventricular diastolic compliance and juxta-cardiac pressures.[12]

Except at extreme values, static measures of CVP do not differentiate patients likely to respond to fluid therapy from non-responders (see Functional Haemodynamic Monitoring section). However, dynamic changes in CVP either in response to volume loading or related to respiration can assist in evaluating volume status.[13] For instance, a steep increase in CVP following volume challenge suggests the heart is functioning on the plateau portion of the Frank-Starling curve. Severe hypotension with a low or normal CVP is unlikely to

Table 16.3 Analysis of central venous pressure waveform

CONDITION	PRESSURE CHANGES	WAVEFORM CHANGES
Tricuspid regurgitation	Increased RA pressure	Prominent *v* wave, *x* descent obliterated, *y* descent steep
Right ventricular infarction	RA and RV pressure elevated. RAP does not fall and may rise in inspiration	Prominent *x* and *y* descents
Constrictive pericarditis	RA, RV diastolic, PA diastolic and occlusion pressures elevated and equalised. RAP may rise in inspiration	Prominent *x* and *y* descents
Pericardial tamponade	RA, RV diastolic, PA diastolic and occlusion pressures elevated and equalised. RAP usually falls in inspiration	Y descent damped or absent

RA = right atrial: RV = right ventricular: RAP = right atrial pressure: PA = pulmonary artery.

be due to acute pulmonary embolism, cardiac tamponade or tension pneumothorax.

CENTRAL VENOUS OXYGEN SATURATION

Central venous oxygen saturation (Scv_{O_2}) is an additional variable that may be monitored with a central venous catheter (continuously or via blood gas analysis of samples). It has been proposed as a marker of tissue wellbeing (oxygenation) and will be discussed in a separate chapter. Having been incorporated into a prospective randomised study of patients with severe sepsis and septic shock (Early Goal Directed Therapy),[14] it is mentioned here only as an example of the scant data relating haemodynamic monitoring to improved survival. Results of multicentre evaluation, including the Australasian Resuscitation in Sepsis Evaluation (ARISE Trial, ANZICS Clinical Trials Group) and Protocolized Care for Early Septic Shock (ProCESS Study, NIH funded), are awaited.

PULMONARY ARTERY CATHETER

Right heart catheterisation using a flow-directed balloon-tipped catheter was introduced by Swan et al in 1970.[15] The ability to monitor sophisticated haemodynamic and gas exchange variables at the bedside appealed to clinicians, and the pulmonary artery catheter (PAC) was rapidly accepted into routine critical care. However, this device is potentially associated with a number of risks (**Table 16.4**).

In 1996 a non-randomised cohort study of PAC use in American teaching hospitals appeared to show that PAC in the first 24 hours increased 30-day mortality (odds ratio 1.24, 95% CI 1.03–1.49), mean length of stay and mean cost per hospital stay.[16] An associated editorial called for a moratorium on PAC use, and for a prospective multicentre trial.[17] Prior to this, pulmonary artery catheterisation was regarded by many as the standard of care. Although a moratorium did not eventuate, the debate contributed to clinical equipoise and paved the way for a number of randomised trials.

A recently edited Cochrane database systematic review of PAC monitoring in adult ICU patients incorporated data from 12 randomised controlled trials in adults, comparing management with and without a PAC.[18] The pooled odds ratio for mortality (28-day, 30-day, ICU, hospital) for the eight studies of high-risk surgery patients 0.99 (95% CI 0.73–1.24) and for the four studies of general intensive care patients was 1.05 (95% confidence interval (CI) 0.87–1.26). A subsequent multicentre trial incorporated protocolised haemodynamic management of patients with acute lung injury compared PAC-guided with CVC-guided therapy.[19] There were no significant differences in 60-day mortality or organ function between groups. Overall, these data suggest that PAC monitoring in critically ill patients is neither associated with increased mortality nor with survival benefit.

On the other hand, data do exist that suggest a differential association between PAC use and mortality

Table 16.4 Complications potentially encountered with pulmonary artery catheterisation with proposed measures for prevention and treatment

COMPLICATIONS	PREVENTION	TREATMENT
DURING INSERTION		
Damage to adjacent structures	As for central venous cannulation.	As for central venous cannulation.
Perforation of pulmonary artery	Ensure balloon inflated throughout insertion. Continuously monitor pulmonary artery waveform. Avoid distal PAC tip position.	As for pulmonary artery rupture below.
Air embolism	Raise venous pressure prior to insertion. Always occlude open ends during insertion. Use sheaths with pneumatic valve. Periodically check and tighten all connections. Remove air from fluid bag and tubing. Dress site with occlusive dressing after removal.	Left lateral Trendelenburg position. Administer 100% oxygen and ventilatory support. If PAC in place tighten all connections and attempt to aspirate air from right atrium or right ventricle. Basic/advanced life support if necessary.
Dysrhythmia (12.5–70%)	Keep balloon inflated during passage from RA to PA. Minimise insertion time.	For sustained ventricular tachycardia, remove PAC from right ventricle. For ventricular fibrillation, remove PAC. Advance life support for persistent dysrhythmia.
Right bundle branch block/ Complete heart block	Avoid PAC insertion in patients with left bundle branch block (LBBB) if possible. Insert PAC with pacing electrodes in patients with LBBB.	Use pacing equipment as required.

Table 16.4 Complications potentially encountered with pulmonary artery catheterisation with proposed measures for prevention and treatment—cont'd

COMPLICATIONS	PREVENTION	TREATMENT
Catheter knotting/kinking/ entanglement	Minimise insertion time. Do not advance catheter against resistance. Check for waveform change from RA to RV or RV to PA after advancing 15 cm; if not withdraw catheter. Limit intravascular PAC insertion depth <60 cm. Use of fluoroscopy.	Check chest X-ray. Pull knot back then remove the sheath and catheter. If no sheath used, a cut-down to vein under local anaesthesia may be required. Exploration by a vascular surgeon is indicated if unsuccessful (5% of occasions).
Valve/chordae damage (~0.9%)	Ensure balloon is inflated during forward passage through the heart and deflated prior to any retraction.	Cardiothoracic consultation.
DURING MAINTENANCE		
Dysrhythmia (37%)	Remove PAC when no longer required.	See above.
Thrombosis	As for central venous cannulation.	As for central venous cannulation.
Pulmonary artery rupture (0.2%)	Risk factors include pulmonary hypertension, anticoagulation and *in situ* duration >3 days. Maintain high level of suspicion. Avoid distal PAC tip position. Minimise wedge procedures. Continuously monitor pulmonary artery waveform – withdraw PAC if spontaneous wedging occurs, inflate with only enough air to change PA to PAOP waveform. Withdraw PAC if PAOP obtained with <1.25 mL air.	Check PAC position on CXR, deflate and pull back. If applicable, stop anticoagulation therapy. Lateral position, affected side down. Selective bronchial intubation. PEEP. Surgical repair.
Pulmonary infarction	As for pulmonary artery rupture.	Check PAC position on CXR, deflate and pull back. Observe.
Infection – including blood stream infection/ bacteraemia (1.3–2.3%) and endocarditis (2.2–7.1%)	As for central venous cannulation.	As for central venous cannulation.
Air embolism	High suspicion of balloon rupture. Avoid repeating failed attempts to inflate.	See above.
Misinterpretation/misuse of data	Anticipation and management of common pitfalls related to: Errors of equipment and data acquisition. Factors affecting data interpretation.	Patient selection, individualisation of therapy, an understanding of potentially useful haemodynamic data, as well as an appreciation of alternative monitoring strategies are suggested.

Source: Based upon information contained in text of reference[64]: Evans DC, Doraiswamy VA, Prosciak MP, et al. Complications associated with pulmonary artery catheters: a comprehensive clinical review. Scand J Surg 2009;98:199–208.

dependent upon severity of illness. Multivariate logistic regression analyses of data from a tertiary care university teaching hospital[20] and from the National Trauma Data Bank (American College of Surgeons)[21] suggest that PAC use may be associated with survival benefit in the most severely ill/injured patients.

Overall, the PAC still finds application in anaesthesia and critical care. It potentially offers unique insights into the right heart and pulmonary circulation. However, its role is under increasing scrutiny, and use continues to decline in favour of less invasive alternatives. It is argued that further studies to determine optimal management protocols and appropriate patient groups are required.[18]

Traditional indications for PAC monitoring have been to:

- characterise haemodynamic perturbation (e.g. distributive, cardiogenic, obstructive and hypovolaemic shock or combinations)
- differentiate cardiogenic from non-cardiogenic pulmonary oedema

- guide use of fluids, vasoactive drugs, fluids (including renal replacement therapy) and diuretics, especially when haemodynamic disturbances are coupled with increased lung water, RV or LV dysfunction, pulmonary hypertension and organ dysfunction.

Contraindications for insertion build upon those for central venous catheterisation. If known in advance, atypical cardiac or vascular anatomy, either congenital or secondary to trauma or surgery, should also be considered. Less invasive monitoring might provide the data that are sought. Also, PAC monitoring does not exclude simultaneous recourse to other monitoring techniques.

MEASURED VARIABLES

The PAC remains unique in its ability to measure right ventricular and pulmonary arterial pressures directly at the bedside. While echocardiography might be considered as a less invasive alternative, it is largely confined to intermittent 'snap-shot' evaluation, and can be technically challenging. Normal pressures are given in **Table 16.5**.

Pulmonary artery occlusion pressure

Measurements of pulmonary artery occlusion pressure (PAOP) should be performed by slow injection of air into the balloon while watching the pulmonary artery waveform. Over-wedging can lead to falsely high occlusion pressures or pulmonary arterial rupture. Less than 1.5 mL air (balloon volume) may be required. Deflation after PAOP measurement should re-establish the normal pulmonary arterial waveform. If not, distal migration has occurred and the catheter should be withdrawn until the waveform is re-established.

PAOP should be measured during end expiration and ideally in end diastole, using the ECG p-wave as a marker. When the catheter wedges in a branch of the pulmonary artery it creates a static column of blood which equilibrates with downstream pressure at the site where it rejoins the flowing pulmonary venous system (the j point).[22] Here the blood is very near the left atrium. PAOP therefore closely approximates left atrial pressure (LAP), which approximates left ventricular end-diastolic pressure (LVEDP). The validity of PAOP as a surrogate of preload depends on a number of assumptions (**Fig. 16.1**); these are often incorrect in critically ill patients and the use of PAOP to reflect preload has been questioned.[23]

Table 16.5 Reference range of measured and derived variables from pulmonary artery catheter

SITE	mmHg	(kPa)
Right atrium mean	−1–7	(0.13–0.93)
Right ventricle: systolic	15–25	(2.0–3.3)
Right ventricle: diastolic	0–8	(0–1.1)
Pulmonary artery: systolic	15–25	(2.0–3.3)
Pulmonary artery: diastolic	8–15	(1.1–2.0)
Pulmonary artery: mean	10–20	(1.3–2.6)
Pulmonary artery occlusion pressure	6–15	(0.8–2.0)

Potential substitutes for pulmonary artery occlusion pressure

Measurement of PAOP requires wedging, which is associated with a number of risks (see Table 16.4). The normal pulmonary artery diastolic pressure (PADP) to PAOP gradient is <5 mmHg (0.65 kPa), so that PADP may normally be used as a close approximation for PAOP. However, tachycardia (>120/min) and conditions that increase pulmonary vascular resistance (such as ARDS, chronic obstructive pulmonary disease and pulmonary embolism) variably increase this gradient, invalidating direct substitution of PADP for PAOP. The relationship between PADP and PAOP tends to be stable over hours. Once this is determined, PADP can be used to track PAOP in the short term without repeated wedge manoeuvres.

Echocardiographic measurements, such as transmitral flow and pulmonary venous flow, can provide evidence of elevated left ventricular filling pressure (the hallmark of diastolic dysfunction).[24] Evidence

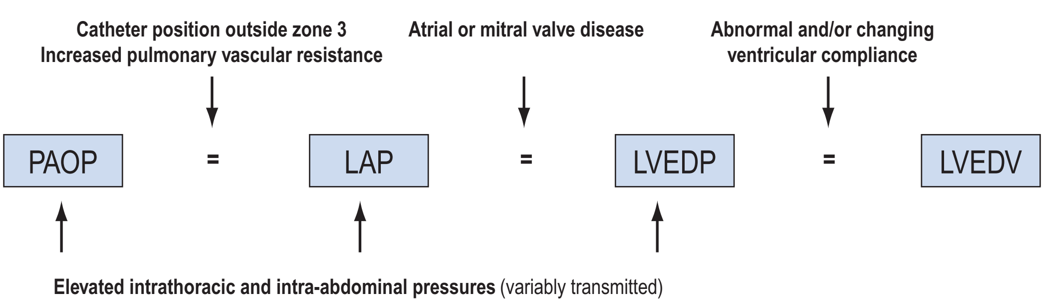

Figure 16.1 Factors affecting the accuracy of PAOP as a measure of preload in critically ill patients. Clinically, LVEDV is usually accepted as a surrogate of preload. PAOP = pulmonary artery occlusion pressure; LAP = left atrial pressure; LVEDP = left ventricular end diastolic pressure; LVEDV = left ventricular end diastolic volume.

Table 16.6 Derived haemodynamic variables

PARAMETER	ABBREVIATION	FORMULA	NORMAL RANGE	UNITS
Mean arterial pressure	MAP	DBP + 0.33 × (SBP − DBP)*	70–105	mmHg
Mean pulmonary artery pressure	MPAP	PADP + 0.33 × (PASP − PADP)*	9–16	mmHg
Mean right ventricular pressure	MRVP	CVP + 0.33 × (PASP − CVP)		mmHg
LV coronary perfusion pressure	LVCCP	DBP − PAOP		mmHg
RV coronary perfusion pressure	RVCCP	MAP − MRVP		mmHg
Cardiac index	CI	CO/BSA	2.8–4.2	$L/min/m^2$
Stroke volume index	SVI	CI/HR	35–70	$mL/beat/m^2$
Systemic vascular resistance index	SVRI	(MAP − CVP)/CI × 79.92	1760–2600	$dyn\ s/cm^5/m^2$
Pulmonary vascular resistance index	PVRI	(PAP − PAOP)/CI × 79.92	44–225	$dyn\ s/cm^5/m^2$
Left ventricular stroke work index	LVSWI	SVI × MAP × 0.0144	44–68	$g\ m/m^2/beat$
Right ventricular stroke work index	RVSWI	SVI × PAP × 0.0144	4–8	$g\ m/m^2/beat$
Body surface area	BSA	Weight $(kg)^{0.425}$ × height $(cm)^{0.725}$ × 0.007184		m^2

* Modern monitors use a more accurate technique; they average the area under the pressure–time curve to estimate mean pressure.
HR = heart rate; CVP = central venous pressure; PAOP = pulmonary artery occlusion pressure; SBP = systolic blood pressure; DBP = diastolic blood pressure; PADP = pulmonary artery diastolic pressure; PASP = pulmonary artery systolic pressure.

increasingly supports the application of such techniques to intensive care patients.[25]

B-type natriuretic peptide (BNP) assay may reflect left ventricular filling pressure, and has demonstrated usefulness in diagnosing cardiac failure in patients presenting to the emergency department with dyspnea. However, preliminary data suggest that BNP is not suitable for evaluating haemodynamic status in critically ill patients.[26]

DERIVED VARIABLES

A number of variables can be derived from the measurements obtained with a standard PAC (see Table 16.5 and **Table 16.6**).

MIXED VENOUS OXYGEN TENSION AND SATURATION

These variables are discussed in Chapter 18 Monitoring oxygenation.

COMPLICATIONS OF PULMONARY ARTERY CATHETERISATION

These are listed in Table 16.4. A catheter may not actually be knotted, despite a chest X-ray appearance to suggest this. If knotting is suspected, other catheters should be removed in reverse order to which they were inserted, and the chest X-ray repeated.

CARDIAC OUTPUT MONITORING

Clinical estimation of cardiac output has been shown to be unreliable until extreme hypotension occurs.[27]

Table 16.7 Classification of methods for evaluating cardiac output in critical care: a variety of techniques primarily estimate stroke volume, multiplication by heart rate calculates cardiac output

CARDIAC OUTPUT	STROKE VOLUME
Fick method (O_2)	Ultrasound • 2D echocardiography (Simpson's method) • Doppler (continuous or pulsed wave)
Indirect Fick method (CO_2) • Partial rebreathing technique	Arterial pressure waveform analysis
Indicator dilution • Thermodilution • Lithium • Indocyanine green • Ultrasound indicator dilution (saline)	Thoracic electrical bioimpedance

A multitude of commercially available devices are approved for cardiac output estimation in critical care. Most devices employ proprietary algorithms. Marketing strategies, patented/trademarked terminology and inconsistencies in nomenclature potentially contribute to confusion. The following discussion of cardiac monitoring techniques attempts to offer the reader an appreciation of fundamental concepts. A classification of techniques is presented in **Table 16.7**.

APPLICATION OF THE FICK PRINCIPLE

The Fick principle is an extension of the law of conservation of mass and states that the amount of a substance taken up by an organ (or the whole body) per unit time is the product of the arteriovenous concentration difference by the blood flow to the organ (or body).

A wide variety of techniques used to measure cardiac output are based upon the Fick principle. The substance measured can include oxygen (Fick method), carbon dioxide (indirect Fick method), or employ an indicator dilution method. Common indicators include thermal energy (thermodilution), lithium and indocyanine green.

THE FICK METHOD

Historically the Fick principle has been applied to determine cardiac output by analysing oxygen uptake from the lungs (direct Fick method). This method requires pulmonary artery catheterisation to sample mixed venous blood. Traditionally, it has been considered the 'gold standard', but in most ICU patients the stringent preconditions for accuracy are not met. Further error is introduced by the elevated oxygen consumption of inflamed lungs. Use is therefore mainly confined to cardiac laboratories.

THE INDIRECT FICK METHOD

The Indirect Fick method employs carbon dioxide (CO_2) as an alternative to oxygen. The use of a partial rebreathing technique, incorporating several assumptions, can be used to eliminate the need to directly measure Cv_{CO_2} with a pulmonary artery catheter.[28,29] The rebreathing values are obtained by introducing an additional 150 mL of dead space into the ventilator circuit (disposable rebreathing loop) and taking measurements once a new equilibrium has been established. Cardiac output can be measured at 3-minute intervals. Assuming that the Cv_{CO_2} concentration does not change significantly throughout the rebreathing period, the terms associated with Cv_{CO2} cancel each other out and are not needed to calculate cardiac output.

Potential issues with the partial rebreathing of CO_2 method include:

- It is unsuitable for non-intubated patients (who have variable tidal volumes and leakage around face-masks).
- Changes in mechanical ventilator settings that alter dead space or ventilation/perfusion relationships may result in an artefactual change in cardiac output measurements. The accuracy of the technique also appears to be challenged by spontaneous mechanically assisted ventilation.
- et_{CO_2} may not accurately reflect change in pulmonary end-capillary and Pa_{CO_2}, especially in chronic lung disease.
- Mathematical models rely upon a series of assumptions that may not be true under certain conditions relevant to critical care.
- There is overall lack of validation in chronic lung disease.

BOLUS THERMODILUTION CARDIAC OUTPUT

This describes the technique utilising a pulmonary artery catheter. It is generally accepted as the de facto clinical gold standard. This reflects applicability at the bedside, clinician familiarity and acceptance of reasonable accuracy.

A bolus injection into the right atrium of cold injectate transiently decreases blood temperature in the pulmonary artery (monitored by a thermistor proximal to the balloon). The mean decrease in temperature (calculated by integrating temperature over time) is inversely proportional to the cardiac output, which can be determined by a modification of the Stewart–Hamilton equation:

$$Q = \frac{V \times (Tb - Ti)K1 \times K2}{Tb(t)\,\mathrm{d}t} \tag{16.1}$$

where Q = cardiac output; V = volume injected; Tb = blood temperature; Ti = injectate temperature; $K1$ and $K2$ = corrections for specific heat and density of injectate and for blood and dead space volumes; $Tb(t)\mathrm{d}t$ = change in blood temperature as a function of time.

This is an indicator dilution method, using thermal energy (temperature) as the indicator. Advantages of using thermal energy as an indicator are that it is non-toxic (temperature of injectate used does not cause thermal injury) and it does not recirculate. Repeat measurements are limited only by volume constraints and the time to regain temperature stability between injections. A clinically significant change in cardiac output cannot be diagnosed with certainty unless there is a difference of approximately 15% between the mean of three cardiac output determinations and the previous mean.[30]

Too much or too little injectate will respectively under-estimate and over-estimate cardiac output. Cold injectate (preferably 0–4°C but up to 12°C is usually accepted) improves the signal to noise ratio, but causes a brief decrease in heart rate, reducing cardiac output while it is being measured (an example of *biological reactance*). Room temperature injectate introduces a small decrement in bias and precision, but has acceptable accuracy. However, the accuracy using room temperature injectate is further degraded at extremes of cardiac index, high ambient temperatures (and thus injectate temperature) or in patient hypothermia.[31]

Respiration causes fluctuations in cardiac output and PA temperature. Reproducibility is improved by taking measurements in expiration, though this may not reflect cardiac output throughout the respiratory cycle. Timing can be difficult and in practice an average

Box 16.1 Causes of inaccurate bolus thermodilution cardiac output measurements

- Catheter malposition
  - Wedge position
  - Thermistor impinging on vessel wall
- Abnormal respiratory pattern
- Intracardiac shunts
- Tricuspid regurgitation (common in mechanically ventilated patients)
- Cardiac dysrhythmias
- Incorrect recording of injectate temperature (minimised by siting an additional thermistor on injection port)
- Rapid intravenous infusions, especially if administered via the introducer sheath
- Injectate port close to or within introducer sheath
- Abnormal haematocrit values (affecting *K2* value)
- Extremes of cardiac output (room temperature injectate)
- Poor technique
  - Slow injection (>4 seconds)
  - Incorrect injectate volume

of three evenly spaced measurements is taken. Causes of inaccurate measurements are listed in **Box 16.1**.

SEMI-CONTINUOUS THERMODILUTION CARDIAC OUTPUT[32]

This method uses the same principles as bolus thermodilution, but allows semi-continuous measurement by employing a thermal filament wrapped around the right ventricular segment of the catheter. This transmits low-power pulses of heat. 'On–off' heat pulses in pseudo-random binary code are delivered in cycles. The downstream thermistor detects the heat pulses, which are then cross-correlated with the input sequence and power (to allow differentiation of thermal signal from noise).

Potential drawbacks of the technique include:

- inaccuracy during thermal disequilibrium,[33] such as rapid infusions of cool fluids or after cardiac bypass
- delay in detecting sudden changes in cardiac output[33]
- magnetic resonance imaging is contraindicated (it can melt the thermal filament)
- electro-cautery can interfere with measurements.

Additional volumetric data

As well as allowing semicontinuous assessment of cardiac output, incorporation of a rapid response thermistor into the PAC allows estimation of right ventricular ejection fraction (RVEF) and right ventricular end-diastolic volume (RVEDV).[34] Thermodilution techniques appear to overestimate RVEDV and underestimate RVEF.[35] However, right ventricular geometry is complex and there are limited options for bedside volumetric evaluation.

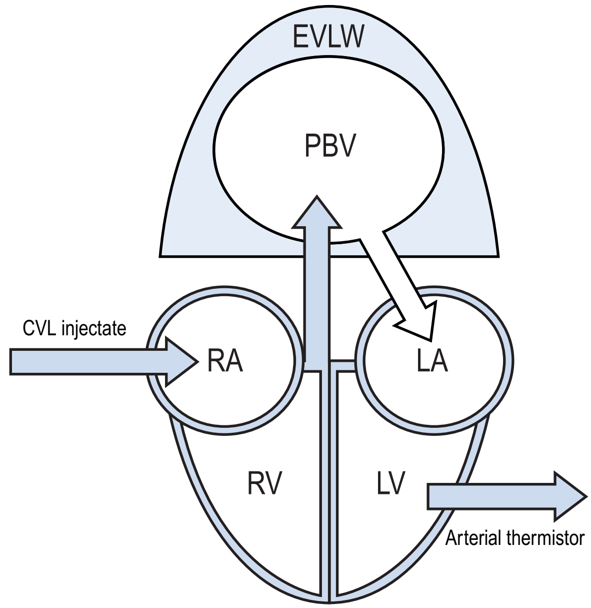

Figure 16.2 Conceptualisation of the transpulmonary mixing chambers of the cardiopulmonary system. Cardiac thermal volumes are proposed to approximate blood volumes at end diastole. CVL = central venous line; EVLW = extravascular lung water; LA = left atrial thermal volume; LV = left ventricular thermal volume; PBV = pulmonary blood volume; RA = right atrial thermal volume; RV = right ventricular thermal volume. Intrathoracic thermal volume (ITTV) is the estimated total thermal volume between the points of central venous injection and peripheral arterial detection, including the EVLW. Pulmonary thermal volume (PTV) is the sum of PBV + EVLW. Intrathoracic blood volume (ITBV) is the sum of RA + RV + PBV + LA + LV, taken to be at end diastole. EVLW = ITTV − ITBV. Global end-diastolic volume (GEDV) is the sum of RAEDV + RVEDV + LAEDV + LVEDV. *(With permission from PULSION Medical Systems SE, www.PULSION.com.)*

TRANSPULMONARY INDICATOR DILUTION

With this technique, thermal and other indicators injected into a central vein are detected in a systemic artery. Because the indicators pass through all chambers of the heart as well as the entire pulmonary circulation, information additional to cardiac output can be gained. In particular, central blood volumes and indices of extravascular lung water can be quantified (**Fig. 16.2**).

Transpulmonary thermodilution[36,37]

A fibreoptic thermistor is usually positioned in the femoral artery at the tip of a modified arterial catheter. Cardiac output is measured by administering a central venous bolus of cold injectate, constructing an arterial thermodilution curve and applying the Stewart–Hamilton equation. The axillary artery can also be used, but placing the sensor in more peripheral arteries such

as the radial causes overestimation of cardiac output. Curves are longer and flatter than PAC curves due to thermal equilibration with intrathoracic blood and extravascular lung water, but are unaffected by the respiratory phase of injection. Measurements are in good agreement with pulmonary thermodilution and direct Fick methods. There is a positive bias of about 5%, perhaps because of indicator loss or because transpulmonary measurements are less affected by the transient decrease in heart rate induced by cold thermodilution.

Mathematical models based upon single- or double-indicator techniques allow estimation of intrathoracic blood volume (ITBV), global end-diastolic volume (GEDV) and extravascular lung water (EVLW).[36]

Unlike CVP and PAOP, ITBV is a volumetric preload index. Interpretation is thus independent of alterations in juxta-cardiac pressures or myocardial compliance, and should be superior to conventional pressure indices. There is experimental and clinical evidence that this is so.[38]

EVLW is a marker of the severity of illness. Following EVLW as a therapeutic end-point may reduce positive fluid balances and ventilator and ICU days.[39] EVLW also appears to offer prognostic information in sepsis and acute lung injury.

GEDV is said to represent the volume of blood in all chambers of the heart at end diastole. Like ITBV, GEDV has been shown to be a more reliable measure of cardiac preload than conventional pressure-based surrogates.[40]

LITHIUM DILUTION CARDIAC OUTPUT[41]

Lithium can also serve as a transpulmonary indicator. The small doses of lithium required are non-toxic and easily measured with an ion-selective electrode. Following injection, there is no significant first-pass loss from the circulation. Blood is sampled from an arterial line via a three-way tap. A peristaltic pump limits sampling to 4 mL/min. After passing through the sensor, blood is discarded.

The main advantage over thermodilution is that more peripheral arteries such as the radial can be used without loss of accuracy. Also, injection can be performed peripherally if central venous access is unavailable. The technique shows good agreement with bolus thermodilution (PAC). It is able to safely and accurately measure cardiac output in adult and paediatric populations.

Potential limitations include:

- It cannot be used in patients receiving lithium therapy (background lithium concentration contributes to overestimation of cardiac output).
- Electrode drift can occur in the presence of high-peak doses of muscle relaxants.
- Abnormal shunts can result in erroneous cardiac output measurements (true for all indicator dilution methods).
- Ex vivo analysis requires disposal of sampled blood.

TRANSPULMONARY DYE DILUTION

Transpulmonary indicator dilution can also be performed using injectable dye, usually indocyanine green. Dye dilution (arterial blood analysis) and pulse dye densitometry (transcutaneous optical analysis, comparable to pulse oximetry) have been applied to cardiac output measurement. Concerns exist regarding the accuracy of the transcutaneous method.[42]

ULTRASOUND INDICATOR DILUTION

Whereas transpulmonary thermodilution relies upon changes in temperature induced by injecting saline (other than body temperature), ultrasound indicator dilution relies upon resultant changes in the velocity of sound transmission. Body temperature isotonic saline is injected into a low-volume arteriovenous loop between existing arterial and central venous catheters. The measured change in ultrasound velocity (blood 1560–1585; saline 1533 m/s) allows formulation of an indicator dilution curve with calculation of cardiac output.[43]

ARTERIAL PRESSURE WAVEFORM ANALYSIS[37]

Estimation of stroke volume by analysis of the arterial pressure waveform, in particular various properties of the pulse pressure (pressure above diastolic) component, has been studied for many years. Devices employ different proprietary algorithms (e.g. pulse contour analysis)[44] to calculate flow (cardiac output) from transduced pressure signals. Generic terminology such as arterial pressure waveform analysis is more broadly applicable.

A number of devices require calibration against another method, after which stroke volume can be trended continuously. Accuracy in the presence of arrhythmia has not been established.

Transpulmonary indicator dilution is the usual method of calibration. Devices that use thermodilution or lithium ion calibration are commercially available.[1]

Disadvantages of such techniques can include:

- Recalibration every few hours is advisable to allow for changes in systemic vascular resistance. This is especially important if there is haemodynamic instability or during the administration of vasoactive drugs.
- Alterations in abdominal pressure or changes in body position, particularly in the obese, can alter aortic compliance, necessitating recalibration.
- Dependence on arterial site – clinical validation studies usually document femoral cannulation.
- Aortic aneurysms and significant aortic regurgitation are both difficult to model and invalidate the technique.

Proprietary algorithms for estimating stroke volume and cardiac output (flow) from pressure-based signals without the need for calibration have been incorporated into a number of devices. The principal advantages of these techniques are ease of use and

non-invasiveness. However, accuracy is impaired in the presence of major changes in vascular compliance, cardiac dysrhythmia, aortic regurgitation, or poor-quality arterial waveform transduction (under- or overdamping, attenuation).[1]

Although only limited published validation data exist, cardiac output can also be estimated from pulse pressure information acquired completely non-invasively using photoelectric plethysmography in combination with a volume-clamp technique (inflatable finger cuff).[45]

ULTRASOUND

Clinical ultrasound and echocardiographic techniques are becoming indispensible in critical care. Echocardiography is increasingly used in the evaluation of haemodynamically unstable patients. Focused haemodynamic protocols are becoming popular for this purpose and complement other monitoring techniques.

Two approaches are available to measure stroke volume (and thereby cardiac output) using sound waves. The first involves the use of echocardiography to measure systolic and diastolic left-ventricular volumes using Simpson's method (summation of discs). Stroke volume is then calculated. Geometric assumptions, user dependence and access to expensive echocardiographic equipment limit the usefulness of this technique for haemodynamic monitoring. The second method uses Doppler techniques to measure stroke volume (**Fig. 16.3**).[46] This methodology forms the basis of numerous monitoring devices. Doppler is less dependent on image quality, shows better agreement with thermodilution and demonstrates good reproducibility.

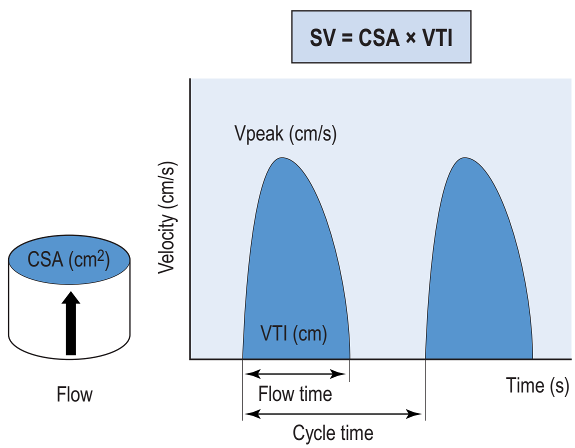

Figure 16.3 Doppler stroke volume calculation. The cross-sectional area of flow (CSA) is calculated as a circle from echocardiographic measurements or nomogram-based estimations. Velocity–time integral (VTI) is the integral of Doppler velocity with regard to time. Stroke volume (SV) is calculated as the product of CSA and VTI (mL/s in this example). Cardiac output is calculated from the product and SV and heart rate. Peak velocity of flow (V_{peak}) is also indicated.

The Doppler principle states that the frequency of reflected sound is altered by a moving target, such as red blood cells. Continuous and pulsed wave Doppler are the main techniques employed to measure flow. Physical principles for the two techniques are similar. Pulsed wave Doppler allows the site of sampling to be specified by transmitting a pulse of sound energy and then 'listening' for a period of time appropriate to catch the signal returning after reflection at the selected depth. With continuous wave Doppler, a piezoelectric crystal transmits the ultrasound beam continuously, while another measures the frequency of reflected waves. The velocities of all the red blood cells moving along the path of the ultrasound beam are recorded. As a result, a continuous wave Doppler recording consists of a full spectral envelope with the outer border corresponding to the fastest moving blood cells. The flow velocity (V) of red cells can be determined from the Doppler shift in the frequency of reflected waves:

$$V = (2F_0 \times \cos\theta)^{-1} \times C\Delta F \tag{16.2}$$

where C is the speed of ultrasound in tissue (1540 m/s), ΔF is the frequency shift, F_0 is the emitted ultrasound frequency, and θ is the angle of incidence. The most accurate results are obtained when the ultrasound beam is parallel to flow ($\theta = 0°$, $\cos\theta = 1$; $\theta = 180°$, $\cos\theta = -1$). However, angles up to 20° still yield acceptable results ($\theta = 20°$, $\cos\theta = 0.94$).

In addition to measuring stroke volume, Doppler assessment of aortic blood flow can provide additional haemodynamic information. For instance, a low duration of aortic velocity signal corrected for heart rate (corrected flow time; FTc) may prompt intravenous fluid challenge.[26,47] The peak velocity of aortic blood flow (V_{peak}) has been proposed as an index of contractility. Also, respiratory variation in V_{peak} (ΔV_{peak}) has been described as a predictor of increased cardiac output in response to fluid challenge.[48]

OESOPHAGEAL DOPPLER MONITORING[37,49]

Oesophageal Doppler measures blood flow velocity in the descending aorta with a Doppler probe (usually 4 MHz continuous wave or 5 MHz pulsed wave depending upon device) incorporated in the tip of a flexible probe. The probe is positioned in the oesophagus about 30–40 cm from the teeth. At this point, the aorta runs parallel to the oesophagus and the systolic cross-sectional area varies least. The probe is rotated to obtain a characteristic aortic signal. The aortic cross-sectional area is either determined from nomograms of age, weight and height, or calculated from a measured diameter (M-mode ultrasound). Calibration against other cardiac output methods is also possible.

Advantages of the technique include:

- Only a short period of training is required. Nurses at the bedside can follow volume challenge protocols guided by Doppler indices.

- The probes (6 mm in diameter) are minimally invasive, and can be inserted nasally or orally.
- Contraindications are few. They include severe agitation, pharyngo-oesophageal pathology, aortic balloon counterpulsation, aortic dissection and severe aortic coarctation.
- Insertion is simple, allowing reduced time to data acquisition and treatment.
- Probes are relatively stable once placed. If displaced they can be repositioned quickly, and can be left in place for days in a sedated, ventilated patient.

Potential disadvantages include:

- Assumptions that descending aortic flow is 70% of total cardiac output and that nomograms accurately determine aortic cross-section can be incorrect. This limits usefulness when there is aortic pathology or compression, or abnormal upper/lower body blood flow distributions.
- Flow in the aorta is not always laminar. Conditions such as tachycardia, anaemia, and aortic valve disease can cause turbulent aortic blood flow and alter velocity measurements.
- Assumptions that the aorta is cylindrical with a fixed systolic cross-section are not always valid. The cross-sectional area of the aorta is actually dynamic and is dependent on the pulse pressure and aortic compliance. This may be particularly relevant in children, where aortic cross-section fluctuates in systole.
- Finding and maintaining optimal probe positioning are important for consistency in trend measurements.
- The probe may be poorly tolerated in non-sedated patients. Oral insertion is usually reserved for intubated patients receiving sedation. Trends toward minimal sedation and shorter duration of endotracheal intubation might decrease the practicality of this technique in many patients.

TRANSCUTANEOUS DOPPLER MONITORING

Externally applied continuous wave Doppler can be used to monitor haemodynamics via transpulmonary (parasternal) and transaortic (suprasternal) windows. If not known or previously measured, flow diameters may be estimated by a proprietary algorithm based upon the linear association between height and cardiovascular dimensions.[50]

Like oesophageal Doppler, this method appears to offer a clinically useful alternative to thermodilution techniques for monitoring cardiac output and its variation.[51] The technique can be used in all age groups and can be comfortably performed in non-sedated patients.

THORACIC ELECTRICAL BIOIMPEDANCE AND BIOREACTANCE[37,52]

An alternating electrical current (high frequency, very low magnitude) is passed through the thorax. Thoracic electrical bioimpedance requires the current to be kept constant while fluctuations in electrical impedance are measured. Six electrodes are usually attached (two in the upper thorax/neck region and four in the lower thorax). These electrodes detect changes in bioimpedance and monitor cardiac electrical signals. The technique is very sensitive to any alteration in position or contact of the electrodes to the patient.

The change in aortic blood flow due to myocardial contraction (stroke volume) is measured from the changes in thoracic bioimpedance through the cardiac cycle. Other factors that contribute to a change in overall thoracic bioimpedance include changes in tissue fluid volume and changes in venous and pulmonary blood volume induced by respiration. Respiratory artefact is eliminated by averaging values over several cardiac cycles using the R–R interval (ECG) as a synchronising signal.

Measuring whole body, rather than truncal, impedance by placing electrodes on wrists and ankles also appears successful.

Inaccuracies can arise from numerous sources that are prevalent in critical care. These include motion artefact, electrical interference, dysrhythmias (including frequent premature atrial contractions and atrial fibrillation) and acute change in tissue water content (such as pulmonary oedema, pleural effusions, or expansion of interstitial fluid). Despite these limitations, it is clinically appealing due to its non-invasive nature.

Bioreactance has built upon the concepts of bioimpedance but, rather than changes in impedance, it measures changes in the frequency of the electrical currents traversing the chest. This potentially improves signal to noise ratio.[1]

FLOW PROBES

In the laboratory, flow probes may be employed to calculate blood flow (including stroke volume and cardiac output). Commercially available systems are ultrasonic or electromagnetic.[53] Though such high-fidelity devices are not readily applied to clinical settings, they are mentioned as the reference or 'gold' standard against which many clinical devices are evaluated experimentally.

STATISTICAL COMPARISON OF CARDIAC OUTPUT MONITORS

Correlation is not an appropriate statistical method for comparing a new measurement device with a reference standard. This is because the new techniques may show high correlation despite being highly inaccurate; for example, the new technique might consistently report cardiac output as double that measured by the reference standard.

A more robust comparison was offered by Bland & Altmann.[54] The Bland–Altmann technique calculates the bias (mean difference between paired measurements), precision (1 standard deviation of the difference

Table 16.8 Variables described as indices of cardiac preload or fluid responsiveness in critically ill patients*

STATIC	DYNAMIC
INTRACARDIAC PRESSURES	RESPONSE TO FLUID CHALLENGE
Central venous pressure (CVP)/right atrial pressure (RAP)	PASSIVE LEG RAISING
Pulmonary artery occlusion pressure (PAOP)	Change in aortic blood flow
CARDIOVASCULAR VOLUMES	Change in pulse pressure
Thermodilution right ventricular end-diastolic volume (RVEDV)	SPONTANEOUS RESPIRATORY EFFORT
Echocardiographic RVEDV	Inspiratory decrease in right atrial pressure (ΔRAP)
Echocardiographic left ventricular end-diastolic area (LVEDA)/ volume (LVEDV)	MANDATORY MECHANICAL VENTILATION
Transpulmonary thermodilution global end-diastolic volume (GEDV)	Systolic pressure variation (SPV)
Transpulmonary thermodilution intrathoracic blood volume (ITBV)	Decrease in systolic pressure (Δ_{down})
DOPPLER	Pulse pressure variation (PPV)
Duration of the aortic velocity signal corrected for heart rate (FTc)	Pulse contour analysis stroke volume variation (SVV)
Respiratory variation in peak velocity of aortic blood flow (ΔV_{peak})	Respiratory variation in peak aortic blood velocity (ΔV_{peak})
	Respiratory change in the pre-ejection period (ΔPEP)
	Respiratory systolic variation test (RSVT)

* Variables have been divided into static and dynamic categories. Static variables are estimates of ventricular preload at a point in time, usually end-expiration. Dynamic variables are characterised by measurement of variation in haemodynamic measurements in response to changes in cardiac loading conditions.
Source: Based on information contained in text of reference: Sturgess DJ, Joyce C, Marwick TH, Venkatesh B. A clinician's guide to predicting fluid responsiveness in critical illness: applied physiology and research methodology. Anaesth Intensive Care 2007;35(5):669–78. Epub 2007/10/16.

between paired measurements) and limits of agreement (2 standard deviations; describes the range for 95% of comparison points). Based on meta-analysis, Critchley & Critchley proposed that the new technique was interchangeable with the reference technique if the limits of agreement were within ±30%.[55] A recent meta-analysis of minimally invasive techniques challenges this arbitrary threshold, suggesting that limits of agreement of up to 45% may be acceptable in clinical practice.[56]

Given that many new monitors now provide continuous measurements, the ability to trend changes in cardiac output has become an important consideration. This information is not provided by the methods discussed so far. This level of statistical analysis is complex and appropriate methodology is still being determined.[57]

FUNCTIONAL HAEMODYNAMIC MONITORING

Functional haemodynamic monitoring builds upon the observation that functional or 'dynamic' haemodynamic variables are better predictors of haemodynamic response to fluid challenge than 'static' variables (**Table 16.8**).[58] The prediction of fluid responsiveness is an attribute of haemodynamic monitoring technology that would allow rational fluid resuscitation with avoidance of the consequences of excess and unhelpful fluid challenge; these consequences may include excess tissue and pulmonary oedema with deleterious impact upon respiratory function, wound healing and abdominal compartment syndrome.[59]

The potential value of fluid responsiveness hinges upon the ability to predict whether a patient's left ventricle is operating on the plateau (preload independent) portion of the Frank–Starling curve at the time of considering fluid challenge. Thus fluid challenge could be avoided, as it will be ineffective and potentially deleterious. Inotropic support should be considered in preference. It is crucial to appreciate that under normal physiological conditions the left ventricle demonstrates recruitable stroke volume (ascending or 'preload dependent' portion of the Frank–Starling curve). Thus prediction of a fluid responsive state does not mandate fluid challenge.

It must also be appreciated that the majority of 'dynamic' variables posed as predictors of fluid responsiveness have been studied in small samples of highly selected patients under restrictive preconditions (including mandatory mechanical ventilation). In particular techniques, such as pulse pressure variation, have been validated only under a number of caveats including the absence of spontaneous respiratory effort, moderate tidal volumes and normal myocardial contractility. Assessing response to fluid challenge or passive leg raising is more generalisable and is more commonly recommended.[60]

PERIOPERATIVE HAEMODYNAMIC OPTIMISATION

The concept of perioperative haemodynamic optimisation (including 'goal-directed therapy') is not novel. However, evidence increasingly supports a role for

haemodynamic monitoring and pre-emptive intervention in high-risk surgical groups, in terms of both reduced morbidity and mortality. The benefit spans monitoring technologies, with potential benefits in terms of reducing mortality as well as surgical complications.[47] Positive results have predominantly followed from protocols incorporating pre- and intraoperative interventions.

MONITORING THE MICROCIRCULATION

Many techniques used to monitor the microcirculation are yet to make the transition to mainstream clinical care. However, there is growing appreciation that perfusion of the microcirculation is adversely affected by many disease states directly relevant to critical care.

Many potential techniques have been studied with varying degrees of success.[61] For reference, a number of techniques for evaluation of perfusion (rather than tissue oxygenation, which is discussed elsewhere) are briefly mentioned here. Clinically, mottled skin, acrocyanosis, delayed capillary refill and increased central to peripheral temperature gradients might disclose an impaired microcirculation. Biomarkers such as lactate and raised plasma hyaluronan (experimental) might also indicate impairment. Laser Doppler flowmetry can be applied to a range of tissues. Microvideoscopic techniques (nailfold videocapillaroscopy; orthogonal polarisation spectral (OPS) and sidestream darkfield (SDF) imaging techniques) can be applied to superficial capillary beds. Except at high levels, blood flow is the major determinant of venous to arterial CO_2 gradient (CO_2 gap). Alternatively, tissue CO_2 can be measured by tissue electrodes, probes or tonometry. Microdialysis and equilibrium analysis allow measurement of molecules from the extracellular environment. These techniques are well suited to quantification of lactate/pyruvate ratio.

Although optimisation of perfusion and oxygenation at a cellular level offers an appealing therapeutic target, a number of practicalities stand in the way. Evaluation of microvascular function at the bedside of critically ill patients remains challenging.[61] Furthermore, many microvascular pathologies may be localised or heterogeneous, in which case the microcirculation being monitored might not offer generalisable data.

Multiple organ dysfunction syndrome

Matthew J Maiden and Marianne J Chapman

Multi-organ dysfunction syndrome (MODS) is a complex process whereby an acute disease precipitates deranged function of a number of organ systems. MODS is encountered commonly in the intensive care unit (ICU) and accounts for 40–50% of deaths.[1,2] Hence, critical care clinicians require a sound understanding of the pathophysiology and management priorities for MODS.

HISTORY

The development of critical care has improved the survival of severely ill and injured patients but with this has come the recognition that organ failure can develop after the initial injury/illness. This was first described during World War II, where soldiers with severe nonthoracic injuries developed respiratory failure and subsequent renal failure. The incidence of this appeared to be related to the severity and duration of pre-hospital hypotension and the term 'shock lung' was used to describe the subsequent respiratory failure. Although hypoperfusion of the organs may have initiated functional impairment, other factors including blood products, microemboli, fat emboli, endotoxin and excessive oxygen were postulated to contribute.

In the 1970s, similar patterns of 'distant' organ failure were reported in critically ill patients following trauma, surgical haemorrhage, abdominal sepsis, pneumonia and pancreatitis. At autopsy, these patients had similar pathological findings (e.g. microvascular thrombi, tracheobronchial casts, pulmonary congestion, hepatic necrosis, gastric ulcers) irrespective of their admission diagnosis.[3] It was therefore proposed that a common pathogenic process may cause multiple organ failure independent of the precipitating event. If this process could be identified and characterised, it may provide a therapeutic target. Although many pathophysiological processes underlying MODS have been described, it is still not clear what the driving force is and why only some patients develop MODS after a precipitating event.

DEFINITION

In 1973, the term 'sequential organ failure' was used to describe the pattern of multiple organ impairment following resuscitation from aortic aneurysm rupture. Over the next two decades, 40 different names were ascribed to this phenomenon of 'organ disease remote from the site of illness/injury'. The terms 'multiple system failure' or 'multiple organ failure' were commonly used; however, each description and definition differed.

A consensus conference in 1992 proposed the term 'multiple organ dysfunction syndrome' (MODS).[4] This term reflects a distinction between 'dysfunction' and 'failure'. 'Failure' implies a dichotomous outcome that is often irreversible whereas 'dysfunction' describes a spectrum of organ impairment that may change over time. The term 'syndrome' was added to describe a pattern of multiple physiological changes that may have a similar pathogenesis. However, this definition does not characterise or quantify the associated organ dysfunction. Over 20 definitions, classifications and scoring systems of multiple organ dysfunction have been described.[5] These have varied according to which organ systems are assessed, which parameters are measured, and the thresholds of these parameters for the organs to be considered dysfunctional.

The MODS and SOFA (Sepsis-related Organ Failure Assessment) scores (**Tables 17.1** and **17.2**; note the similarity between the scores) were independently developed after the consensus definition of MODS and are commonly used to clinically define the syndrome. Rather than predicting mortality, they were primarily established to describe the severity of MODS and the changes in organ function over time.[6,7] The scores use an equally weighted variable for each of six organ systems that were chosen because they had a strong relationship with mortality and were least influenced by treatment. The score at ICU admission and the change in score over the course of ICU stay strongly correlates with mortality rate with both the MODS and SOFA scores performing similarly.[8] However, these scoring systems use only one parameter for each organ system and thus may underscore patients displaying other features of organ dysfunction. These scores continue to be used to standardise reporting of MODS and provide a quantitative measure of severity that can be followed over time.

AETIOLOGY OF MODS

MODS occurs most commonly as a consequence of the inflammatory response to infection (i.e. sepsis).

Table 17.1 MODS score

MODS SCORE	0	1	2	3	4
Respiratory[a] *(P_{O_2}/Fi_{O_2})*	>300	226–300	151–225	76–150	≤75
Renal[b] *(serum creatinine µmol/L)*	≤100	101–200	201–350	351–500	>500
Hepatic *(serum bilirubin µmol/L)*	≤20	21–60	61–120	121–240	>240
Cardiovascular[c] *(PAR)*	≤10.1	10.1–15.0	15.1–20.0	20.1–30.0	>30.0
Haematologic *(platelet count × 10^3/ml)*	>120	81–120	51–80	21–50	≤20
Neurologic[d] *(Glasgow Coma Score)*	15	13–14	10–12	7–9	≤6

[a]P/F ratio is calculated without reference to the use or mode of mechanical ventilation, and without reference to the use or level of positive end-expiratory pressure;
[b]serum creatinine measured without reference to the use of dialysis;
[c]Pressure-adjusted heart rate (PAR) is calculated as the product of heart rate (HR) multiplied by the ratio of the right atrial (central venous) pressure (RAP) to the mean arterial pressure (MAP): PAR = HR × RAP/MAP;
[d]The Glasgow Coma Score is preferably calculated by the patient's nurse, and is scored conservatively (for the patient receiving sedation or muscle relaxants, normal function is assumed, unless there is evidence of intrinsically altered mentation).

Table 17.2 SOFA score

SOFA SCORE	1	2	3	4
Respiratory *(P_{O_2}/Fi_{O_2})*	<400	<300	<200 With respiratory support	<100 With respiratory support
Renal *(serum creatinine µmol/L or urine output)*	110–170	171–299	300–440 or <500 ml/day	>440 or <200 ml/day
Hepatic *(serum bilirubin µmol/L)*	20–32	33–101	102–204	>204
Cardiovascular[a]	MAP < 70mmHg	Dopamine ≤ 5 or Dobutamine (any dose)	Dopamine > 5 or Epinephrine ≤ 0.1 or Norepinephrine ≤ 0.1	Dopamine > 15 or Epinephrine > 0.1 or Norepinephrine > 0.1
Hematologic *(platelet count × 10^3/ml)*	<150	<100	<50	<20
Neurologic *(Glasgow Coma Score)*	13–14	10–12	6–9	<6

[a]Adrenergic agents administered for at least 1h (doses given are in µg/kg/min).

However, almost any disease that invokes tissue injury may progress to MODS (**Box 17.1**).

PATHOGENESIS

MODS is a systemic process with complex pathophysiology. Although inflammation appears to be central to the development of MODS, the extent to which other processes contribute varies according to the precipitating disease, the stage of disease/recovery, the functional reserve of the organs, and the type and timing of the treatments provided. The pathogenesis of MODS is best conceptualised as a complex dynamic non-linear system involving a large number of variables that are highly interdependent (**Fig. 17.1**).[9]

Box 17.1 Diseases that can progress to MODS

Sepsis

Non-sepsis
- Major trauma
- Burns
- Pancreatitis
- Aspiration syndromes
- Extracorporeal circulation (e.g. cardiac bypass)
- Multiple blood transfusion
- Ischaemia–reperfusion injury
- Autoimmune disease
- Heat-induced illness
- Eclampsia
- Poisoning/toxicity

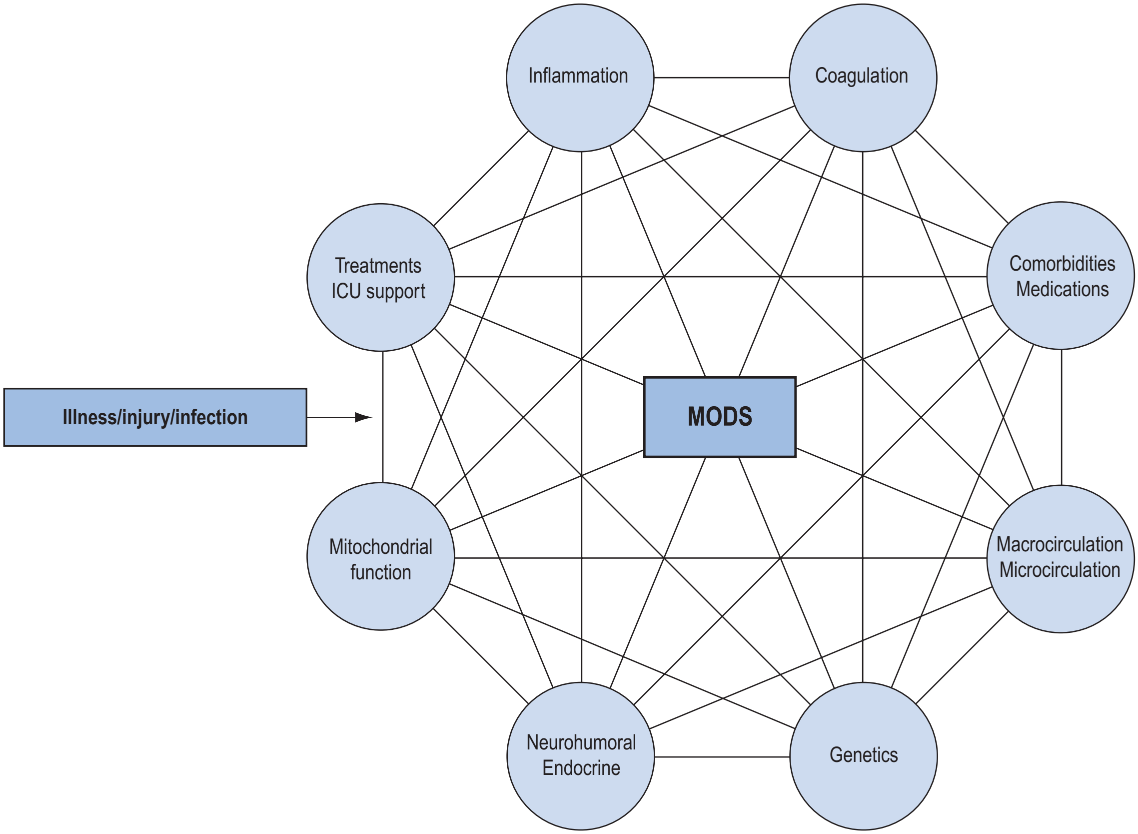

Figure 17.1 MODS results from a complex interaction of a number of different pathogenic processes.

INFLAMMATION

Inflammation is essential to contain infection and for tissue repair. However, the inflammatory response to injury/illness/infection may become 'dys-regulated' during critical illness.[10] Increased levels of pro-inflammatory mediators are associated with worsening organ dysfunction and MODS can be reproduced experimentally by infusion of inflammatory cytokines. As a systemic inflammatory response appears to be central to the development of MODS, the term 'systemic inflammatory response syndrome' (SIRS) was defined in conjunction with the definition of MODS (**Box 17.2**).[4] However, SIRS is non-specific and provides little information about what is provoking the inflammation or the likelihood of progression to MODS.

Many inflammatory mediators have been characterised over the last 50 years (**Box 17.3**). They are released from a variety of inflammatory cells and interact with the immune, endocrine and nervous systems to mediate host defence and tissue repair.

The complex interaction between these mediators has led to the search for common pathways in inflammation that may become therapeutic targets. Intracellular cell signalling molecules that modulate production of cytokines have been the focus of recent research.

Nuclear factor-κB (NF-κB) is a co-factor involved in the transcription of genes that encode inflammatory proteins, apoptotic signalling pathways and nitric oxide production. NF-κB is preformed in the cytoplasm and is activated when the inhibitory subunit (IκBα) is cleaved off, allowing NF-κB to translocate to the nucleus. NF-κB levels are increased in sepsis in proportion to severity.[11]

Box 17.2 Systemic inflammatory response syndrome (SIRS)

Systemic inflammatory response syndrome (SIRS) is defined by the presence of two or more of the following:

1. Temperature >38°C or <36°C
2. Heart rate >90 beats/min
3. Respiratory rate >20 breaths/min or hyperventilation with Pa_{CO_2} <32 mmHg (4.2 kPa)
4. White cell count >12 000 or <4000 cells /µL or >10% immature forms.

Box 17.3 Inflammatory mediators associated with MODS

Interleukin-1β
Interleukin-6
Interleukin-8
Tissue necrosis factor-α
Interferon-γ
Colony stimulating factors
Eicosanoids/platelet-aggregating factor
Soluble adhesion molecules
Complement activation
Heat shock proteins
Free radicals
Pro-calcitonin

Toll-like receptors (e.g. TLR2, TLR4) are activated by bacterial products and necrotic cells and they in turn activate NF-κB and other factors that transcribe inflammatory mediators. The process of TLR activation differs between microbial and non-microbial precipitants.[12] Preclinical studies targeting the non-microbial activation pathways have yielded less organ dysfunction while maintaining anti-microbial efficacy.

High mobility group box protein 1 (HMGB-1) is an evolutionary conserved protein that potentiates binding of inflammatory mediators to inflammatory cells. It also acts as a nuclear co-factor that enhances DNA transcription of inflammatory mediators. Plasma levels of HMGB-1 increase in sepsis and trauma in proportion to the severity of the illness or injury. In experimental studies, anti-HMGB-1 attenuates the inflammatory response to infection, autoimmunity, ischaemia and trauma.[13]

COMPENSATORY ANTI-INFLAMMATORY RESPONSE SYNDROME (CARS)

To ensure a controlled inflammatory response, inflammatory cells also release mediators with anti-inflammatory effects (e.g. IL-4, IL-10). Just as pro-inflammatory mediators may become excessive, the anti-inflammatory response may become predominant, resulting in a state of immunosuppression and anergy.[14] This anti-inflammatory response has been termed the 'compensatory anti-inflammatory response syndrome' (CARS) and is typically encountered some time after the initial inflammatory response.[15] Immunological changes include apoptosis of lymphocytes, release of IL-10, which suppresses TNF-α, decreased cytokine production and down-regulated HLA receptors on monocytes.[16] This relative immunosuppression is often a feature of MODS and is thought to account for why many patients develop iatrogenic infections with organisms that are usually commensal or of low virulence (e.g. *Candida*, *Pseudomonas*, *Stenotrophomonas*, *Enterococcus*).

COAGULATION

The clotting system can be triggered by tissue factor, endotoxin, bacterial antigens and cytokines. Thrombin is produced at the site of infection/injury to isolate infectious sources and initiate tissue repair. However, products of the clotting cascade are pro-inflammatory and the clotting system is central in the inflammatory response. For example, activation of the thrombin receptor induces transcription of NF-κB and stimulation of pro-inflammatory sequelae.

Coagulation is normally controlled by the endogenous anti-coagulant factors anti-thrombin III (AT-III binds to thrombin and endothelium to release endothelial prostacyclin and inhibit platelet aggregation) and protein C (which complexes with protein S to inhibit Va and VIIIa). Levels of these anti-coagulants fall during critical illness and their reduction is proportional to the severity of MODS.[17]

NEUROHUMORAL CHANGES

The autonomic system is closely intertwined with the inflammatory response. The sympathetic and parasympathetic nervous systems innervate lymphoid organs and most immune cells have neurotransmitter receptors. Neural stimulation of the immune cells inhibits cytokine release and suppresses the immune response. Some immune mediators also act as neurohormones providing neural feedback regarding the inflammatory state (**Fig. 17.2**).[18,19]

The 'stress response' to critical illness involves release of the adrenal hormones. This is controlled by hypothalamic secretion of corticotropin-releasing hormone (CRH) under direct neural control and modulated by circulating cytokines. Inadequate hypothalamic–pituitary–adrenal response to critical illness or glucocorticoid resistance may contribute to MODS.

Changes to thyroid metabolism occur during MODS. In health, thyroxine (T_4) is metabolised to the metabolically active tri-iodothyronine (T_3), whereas during critical illness changes to the de-iodination pathways favour production of the biologically inactive reverse-T_3. The consequential fall of plasma T_3 levels is proportional to the severity of MODS and is predictive of mortality.[20]

MACROCIRCULATORY CHANGES

Inadequate circulation of blood resulting in reduced cellular oxygen delivery (DO_2) can lead to anaerobic metabolism and impaired function. This state of circulatory shock contributes to MODS.

Vascular tone is often reduced in MODS with excessive nitric oxide being a well-characterised culprit. Endothelial nitric oxide synthase (iNOS) is induced by many different inflammatory mediators. The nitric oxide (NO) produced is toxic to micro-organisms, acts as an inflammatory signal, produces vascular smooth

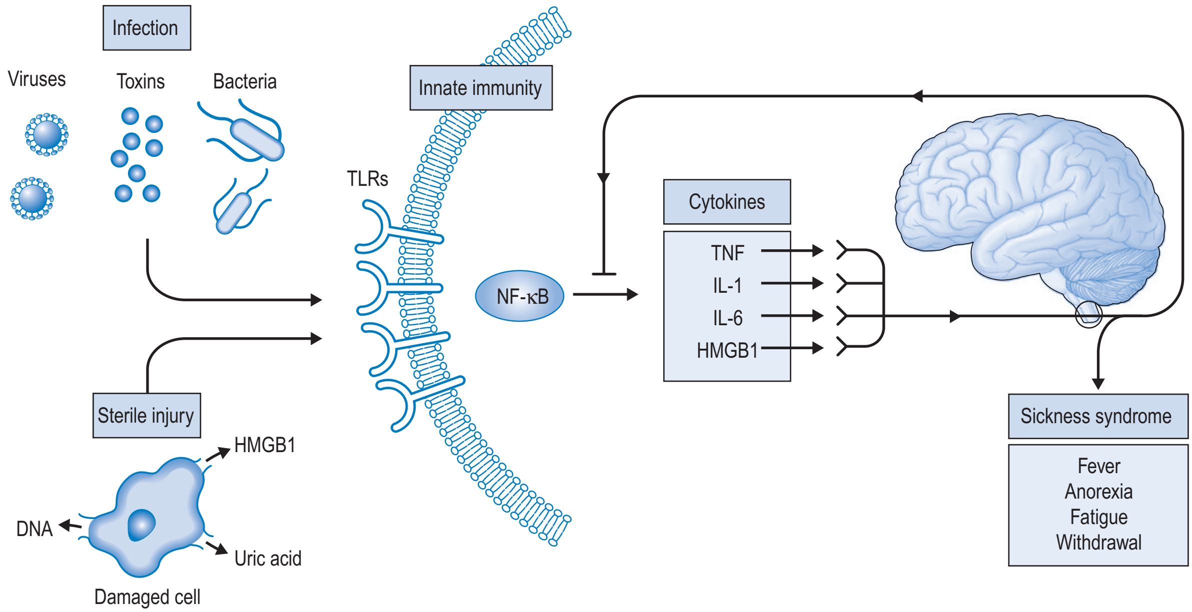

Figure 17.2 Neurohumoral factors influence the response to illness/injury. *(Adapted from Tracey KJ. Understanding immunity requires more than immunology. Nat Immunol 2010;11(7):561–4.)*

muscle relaxation and maintains patency of the microcirculation. However, excessive NO also leads to 'vasoplegia' with low systemic arterial pressures, venodilation and altered blood flow into the organs.

Maintaining sufficient blood circulation is essential for normal organ function. However, attempts to prevent MODS by providing supranormal DO_2 by transfusing red cells or increasing cardiac output with dobutamine have not improved outcomes.[21] Furthermore, clinical studies of agents that inhibit iNOS or antagonise NO have shown haemodynamic benefit but have increased mortality.[22]

MICROCIRCULATORY CHANGES

Using spectral imaging techniques, it has been observed that reduced blood flow through the microcirculation is associated with organ failure and death (**Fig. 17.3**).[23] Microvascular thrombi, reduced red blood cell deformability and increased blood viscosity contribute to reduced microvascular flow.[24] Excessive NO leads to mismatched microvascular flow and shunting.[25] Vascular endothelial disruption increases microvascular permeability favouring formation of interstitial oedema, which further restricts diffusion between the cell and the microcirculation.

APOPTOSIS

Apoptosis is controlled cellular death without provoking inflammation. It is an essential process for normal coordinated function of populations of cells and is involved in cell ageing, immune regulation, epithelial cell turnover and resolution of inflammation. During critical illness, apoptosis is increased in lymphocytes and in cells that typically have a barrier function (e.g. gut epithelium, vascular endothelium).[26] This increases susceptibility to further insults. In contrast, apoptosis of neutrophils is delayed and may lead to an exaggerated inflammatory response.[27] Caspases are central in the regulation of apoptosis and may provide a therapeutic target.

MITOCHONDRIAL DYSFUNCTION

Cell necrosis is an uncommon finding in post-mortem examination of organs that have failed due to MODS. This suggests that processes leading to MODS are primarily a functional disorder rather than structural. Cells may enter a state of 'hibernation' where metabolic activity is reduced. Changes in mitochondrial respiration seen in MODS may be induced by alterations in humoral factors that have metabolic effects (e.g. thyroid hormone, glucocorticoids, catecholamines and cytokines).[28] The cell subsequently fails to utilise available O_2, leading to cellular dysoxia and cellular dysfunction contributing to organ dysfunction.[29,30]

CO-MORBIDITIES

An important consideration in the development of MODS is the patient's premorbid organ function. Patients with pre-existing organ disease are more likely to have further deterioration of organ function as the

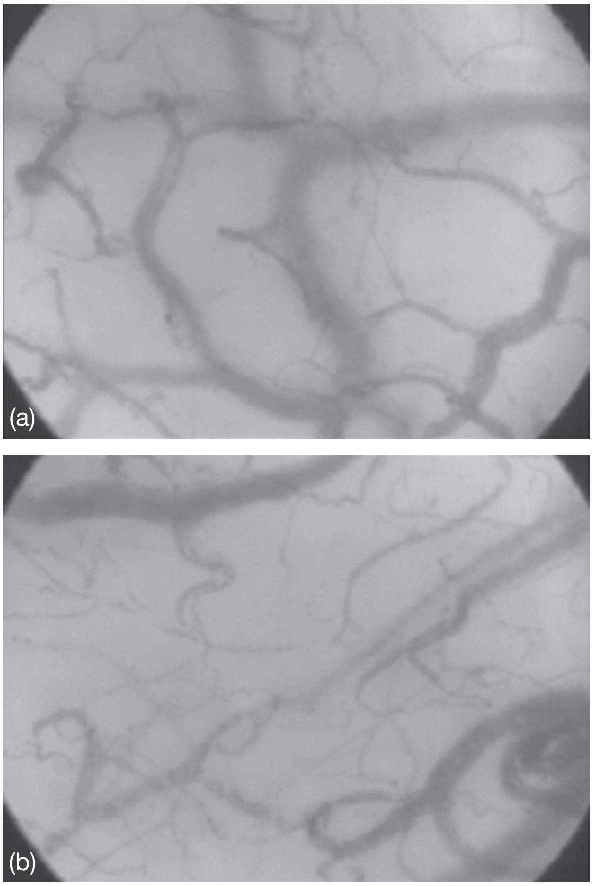

Figure 17.3 Sublingual microcirculatory changes seen in sepsis-induced MODS. (a) Healthy volunteer, and (b) a patient with septic shock. Note the rich density of large and small vessels in the healthy volunteer and the decrease in density of small vessels in sepsis. *(Reprinted with permission of the American Thoracic Society. result of acute critical illness (e.g. compromised respiratory reserve in fibrotic lung disease, limited renal function in diabetic nephropathy, reduced marrow response in chronic leukaemia, impaired hepatic function in alcoholic liver disease). These patients will have a lower threshold for developing MODS.

IATROGENESIS

The recognition of MODS corresponded with the development of intensive care supports. It may be that some ICU interventions actually increase the risk of developing MODS or continue to drive the process once it is initiated. For example, the ARDSnet study revealed that 'large tidal-volume ventilation' stimulates the release of pulmonary cytokines leading to worsening lung injury and increased risk of death.[31] ICU patients are now ventilated with smaller tidal volumes. Other ICU interventions such as type of parenteral fluids, immobility, artificial cooling, extracorporeal circulatory support, inotropes, medications, nutrition supplements and blood products may contribute. Providing evidence-based supportive care is a vital aspect of preventing MODS.

GENETICS

For similar disease precipitants and patient baseline characteristics, the phenotypic presentation of MODS differs. Why some patients develop mild organ dysfunction whereas others progress to fulminant MODS may be accounted for by a patient's genotype. For example, differences in genes coding for TNF, TLR, NF-κB, interleukin-1 receptor kinase and caspase-12 have been related to severity of organ dysfunction and extent of ICU supports required following sepsis.[32] Similarly, in patients undergoing elective abdominal aortic aneurysm repair, analysis of preoperative leucocyte genes predicted which patients subsequently developed MODS.[33] Differences in gene expression and proteomic responses may help identify which patients are at risk of MODS and may guide future treatment.

THE GUT IN MODS

The gut and its enteric micro-organisms have been proposed to provide an inflammatory focus during critical illness. Normally these organisms remain commensal due to bowel wall integrity and maintenance of the normal microflora ecosystem. However, when normal conditions are disturbed (e.g. bowel mucosal changes, altered gastric pH, antimicrobial use, overwhelmed reticuloendothelial macrophages), the enteric organisms can invade and perpetuate an inflammatory response. The gut has been described as the 'motor' of MODS and conceptualised as an 'undrained abscess'.[34] However, decontamination of the gut in critical illness remains controversial.

CLINICAL FEATURES OF MODS

The hallmark of MODS is the presence of SIRS with progressive physiological dysfunction in two or more organs.[4] However, there is no one typical constellation or timecourse of organ dysfunction that describes MODS. Some patients may develop only mild organ dysfunction that, with supportive treatment, resolves in days, whereas others can develop fulminant MODS progressing rapidly to death. Which organs become dysfunctional and the timing of their dysfunction depend on the patient's age and phenotype, the inciting injury/illness, premorbid organ function, extent and

duration of physiological derangement and the treatments provided.

Identification of MODS as a discrete clinical syndrome has been difficult due to lack of agreement about what characterises an organ dysfunction. There are many ways of measuring organ dysfunction: clinical features, monitored physiological derangement and altered biochemical markers. Each organ system can manifest dysfunction in many different ways. For example, the respiratory system can be considered dysfunctional based on hypoxia (e.g. $Pa_{O_2}:Fi_{O_2}$ ratio), hypercarbia, reduced compliance, radiological change, extent of ventilatory supports or lavage fluid content. The processes that lead to changes in these parameters can be quite different and defining an organ dysfunction based on one variable alone is inadequate to describe the full spectrum of disease.

THERAPIES FOR MODS

The risk of MODS is related to the severity of the precipitating illness/injury, the extent of presenting physiological disturbance, degree of premorbid organ dysfunction and time to definitive care.[35,36] Hence the priorities in the treatment of MODS are:

1. Early recognition of illness
2. Early resuscitation
3. Early definitive treatment
4. Intensive organ support
5. Consideration of premorbid disease
6. Prevention of secondary insults.

The focus of management must be on the immediate treatment of the inflammatory focus (e.g. remove source of sepsis, repair injured tissue, control blood loss, debride burns, stabilise long-bone fractures). Aspects relating to early recognition of the deteriorating patient, resuscitation, specific disease treatments and the methods of organ support are covered in other chapters.

Specific therapies that target the pathogenesis of MODS continue to be extensively studied. Each of the pathophysiological processes described earlier has been targeted in preclinical and clinical trials. However, despite early promise in preclinical studies, no therapy has proven clinical efficacy in the treatment of MODS. The lack of a 'magic bullet' for treatment of MODS is not surprising given the complexity and variability of the pathophysiology, the lack of standardised treatments for some diseases and uncertainty regarding optimal timing of adjunctive therapy.

INFLAMMATION-MODULATING THERAPIES

The pro-inflammatory mediators associated with MODS have been an attractive therapeutic target. In preclinical studies many of these agents have provided physiological benefit, reduced severity of organ dysfunction and improved mortality. However, when these therapies progressed to clinical trials, none have provided benefit and some have worsened outcomes. For example, TNF-α was one of the first cytokines studied as it is released early in the inflammatory process and reducing its effect may attenuate the inflammatory process. Preclinical studies of TNF-α antibodies and soluble TNF-receptors in bacteraemic primates suggested that neutralising TNF-α improved organ function and reduced mortality. However, not only did clinical trials fail to show a benefit but higher doses increased mortality.[37] Similarly, the following agents have shown encouraging results in preclinical trials but no efficacy or adverse outcomes in subsequent clinical studies: endotoxin antibodies, non-steroidal anti-inflammatory drugs, IL-1 receptor antagonists, PAF antagonists, bradykinin antagonists, interferon-γ, nitric oxide synthase inhibition, NO antagonists, AT-III concentrate and activated protein C.[38,39]

The lack of clinical efficacy of immunomodulating therapies for MODS may reflect an inappropriate focus on the harmful effects of cytokines rather than their beneficial role. While inflammatory mediators are associated with MODS, they are also vital for control of infection, tissue repair and healing. Furthermore, the pro-inflammatory mediators also have downstream effects that eventually attenuate inflammation. Although elevated concentrations of pro-inflammatory cytokines are clearly associated with MODS, reduced levels are also associated with increased mortality.[40,41] The inflammatory response involves a very complex interplay of pro- and anti-inflammatory mediators and it is not surprising that targeting one pro-inflammatory mediator has not proven effective.

Future therapies to assist with recovery from MODS may aim to control excess inflammation without interfering with the essential components of the inflammatory process. Agents that modulate the inflammatory process without diminishing anti-microbial mechanisms are currently being investigated.

HUMORAL THERAPY

The role of endocrine manipulation during MODS remains uncertain. 'Tight' blood glucose control with intensive insulin therapy was efficacious in a single centre study of predominantly surgical patients.[42] However, when these blood glucose targets were applied in medical patients in the same centre and in subsequent multicentre studies, no benefit was found and some revealed greater mortality.[43,44]

Glucocorticoids have been a popular experimental therapy. 'High-dose' steroid treatment is known to suppress the inflammatory response but when trialled in critically ill patients with MODS proved to be harmful.[45] As MODS may be associated with relative adrenal insufficiency and/or glucocorticoid resistance, lower-dose steroid treatment has been investigated. Initial

studies suggested that septic patients with limited response to ACTH administration had mortality benefit from steroid replacement.[46] However, in the CORTICUS trial, which studied a broader group of septic patients, hydrocortisone did not provide mortality benefit.[47] Whether or not steroid administration is beneficial in sepsis/MODS continues to be debated.

In contrast to steroids, thyroid hormone replacement during MODS has received little attention despite markedly reduced T_3 concentrations. Clinical trials in cardiothoracic ICU patients with low T_3 suggested replacement improves cardiovascular function.[48] This is an area that merits further investigation.

NUTRITION

MODS is a hypercatabolic state and nutritional support is required to ensure adequate energy, protein, fatty acids and trace elements. Nutrition is most safely provided via the gut and delivery by this route may improve intestinal mucosa function.[49] However, the ideal energy delivery and macronutrient composition of nutrition remain unclear. Furthermore the efficacy of supplementing feeds with amino acids (e.g. arginine, glutamine), nucleotides, fatty acids (e.g. omega-3, γ-linoleic acid) and antioxidants (e.g. selenium) is unproven.

OUTCOMES

Despite an increasing prevalence of ICU admissions due to sepsis, outcomes from MODS appear to have improved over time.[50,51] Similarly, patients admitted to ICU with major trauma are now older and have increased injury severity scores but a lower incidence and severity of MODS.[52] As no specific therapies have been developed that 'treat' MODS, the improved outcomes are likely to reflect a greater awareness of the diseases that can progress to MODS, the importance of timely resuscitation and treatment and the application of evidence-based supportive care.

Many questions remain regarding the definition, pathogenesis, diagnosis and treatment of MODS. There has not been a consensus conference on this topic since 1992.[4] Improved clarity in this area is a priority for the ICU community.

Monitoring oxygenation

Thomas J Morgan and Balasubramanian Venkatesh

THE ROLES OF OXYGEN IN AEROBIC ORGANISMS

Oxygen has several physiological roles:

1. *Bioenergetics:* aerobic mitochondrial respiration accounts for 90% of oxygen consumption, generating adenosine triphosphate (ATP) by oxidative phosphorylation. Mitochondrial electron transfer oxidase systems provide the fundamental machinery, in particular the cytochrome oxidase of complex IV. Oxygen acts as a terminal electron acceptor, combining with two protons to produce water.
2. *Biosynthetics:* oxygen transferase systems incorporate oxygen into substrates, such as prostanoids, catecholamines and some neurotransmitters.
3. *Biodegradation and detoxification reactions:* these mixed function oxidase reactions require oxygen and a co-substrate (e.g. NADPH). The cytochrome P-450 hydroxylases are examples.
4. *Generation of reactive oxygen species:* these are essential anti-microbial defences deployed by neutrophils and macrophages.[1]

'HYPOXIA' AND 'DYSOXIA'

The term 'hypoxia' connotes tissue oxygen deficiency, and has largely superseded the older term 'anoxia'. In 1977 'dysoxia' was introduced as a broader term signifying any form of oxygen-limited cytochrome turnover causing progressive ATP depletion.[2] By this definition dysoxia can occur as a result of hypoxia, but can also be present in states of normal or supranormal oxygen tissue availability.

THE SPECTRUM OF DYSOXIA

1. 'Stagnant' hypoxia, where the primary abnormality is reduced tissue blood flow
2. Oxygen transport block at capillary, interstitial or intracellular levels
3. 'Hypoxaemic' hypoxia, where the primary abnormality is a low arterial oxygen tension
4. 'Anaemic' hypoxia, where the primary abnormality is a low haemoglobin concentration
5. 'Cytopathic' dysoxia, a phenomenon often attributed to sepsis and defined as abnormal cellular oxygen utilisation despite adequate oxygen delivery[3]
6. Oxygen toxicity, defined as abnormal cell function due to high oxygen tensions.

CONSEQUENCES OF TISSUE HYPOXIA

As tissue P_{O_2} falls, biosynthetic and biodegradation systems fail first. Aerobic ATP production initially adjusts to match ATP consumption by several adaptive metabolic mechanisms including increased glycolysis.[4] Cell signalling by reactive oxygen species, released at mitochondrial complex III, activates hypoxia-inducible factor-1, a transcription factor up-regulating genes important in hypoxic cell survival.[5] Oxidative phosphorylation itself begins to fail when intracellular P_{O_2} < 0.1–1 mmHg (0.013–0.13 kPa), equivalent to an extracellular P_{O_2} < 3–5 mmHg (0.39–0.65 kPa). Stopgap ATP production continues by anaerobic glycolysis, but without correction of dysoxia there is progressive lactic acidosis and eventual cell death by apoptosis and necrosis. On reoxygenation, a further release of reactive oxygen species causes oxidant stress, often overshadowing the hypoxic insult.[1]

THE OXYGEN CASCADE

In unicellular organisms, oxygen reaches the mitochondria across a short diffusion path with a steep partial pressure gradient. In multicellular animals the much longer diffusion path traverses a series of stepped partial pressure reductions known as the oxygen cascade. As a result, oxygen tensions in intracellular organelles remain above the anaerobic threshold.

Important steps in the oxygen cascade include:

1. Inspired gas
2. Alveolar gas
3. Arterial blood
4. Microcirculation
5. Interstitium
6. Mitochondria and other intracellular organelles.

The cascade can be jeopardised at any step. If more than one step is involved there is oxygen deprivation amplified downstream in mitochondria and other

intracellular organelles. In this chapter we will consider how oxygenation can be monitored at strategic points along the cascade.

INSPIRED GAS

Monitoring the fraction of inspired oxygen (Fi_{O_2}) is necessary to prevent the adverse effects of both hypoxaemia and excess oxygen. The inspired oxygen tension (Pi_{O_2}) of humidified gas is determined by the Fi_{O_2}, the barometric pressure (BP) and the saturated vapour pressure of water (47 mmHg (6.11 kPa)):

$$Pi_{O_2} = Fi_{O_2} \times (\text{BP} - 47) \qquad (18.1)$$

Gas supply pressures are monitored continuously. Ventilators incorporate input pressure alarms and oxygen analysers within the inspiratory module to identify oxygen source failure. Direct measurement of circuit oxygen concentration can be added.

TRANSFER OF INSPIRED GAS TO ALVEOLI

Communication is open between oxygen delivery system and pulmonary alveoli if:

1. There are no signs of upper airway obstruction (Ch. 29)
2. Expired tidal and minute volumes and airway pressures for the ventilated patient are within correctly set alarm limits (Ch. 31)
3. There is an appropriate end-tidal CO_2 waveform (Ch. 38).

ALVEOLAR GAS

In a patient receiving 100% oxygen, alveolar P_{O_2} in individual lung units can range from <40 mmHg to >600 mmHg (<5.2 – >78 kPa). Consequently, end-tidal P_{O_2} monitoring is of little value.

DISTRIBUTION OF ALVEOLAR VENTILATION

Clinicians routinely track chest movement, auscultate air entry, and examine plain chest radiographs. Intermittent CT scanning can reveal occult overdistension,[6] but has logistic disadvantages and is a significant radiation hazard. Electrical impedance tomography shows promise as a real-time non-invasive monitor of recruitment, overdistension and regional lung mechanics. With contrast injections of hypertonic saline it has additional potential for assessment of regional lung perfusion.[7,8]

MATCHING OF VENTILATION AND PERFUSION

For efficient gas exchange, the majority of lung units must receive well-matched alveolar ventilation and perfusion with most V/Q ratios close to unity, but even in health there is some spread to lower and higher ratios. When lungs are diseased, the proportion of lung units with high and low V/Q ratios increases. The adult lung contains at least 100 000 individual gas-exchanging units[9] whose V/Q ratios potentially range from zero to infinity. Such complexity resists simple bedside quantification. The gold standard is the multiple inert gas technique (MIGET), which describes a 50-compartment lung model. By measuring the retention and elimination of six inert gases of varying solubility infused in pre-equilibrated saline, MIGET quantifies the distribution of ventilation and perfusion to 50 lung units spanning a range of V/Q ratios from zero to infinity.[9,10] However, lung models with fewer compartments may suffice for clinical quantification of lung pathophysiology, with the advantage that they can be more easily applied at the bedside. Instead of inert gas infusions, stepped Fi_{O_2} changes can serve as a forcing function while blood gas values and end-tidal gas concentrations are tracked (or pulse oximetry in the least invasive versions).[11–13]

THE ‘IDEAL’ ALVEOLUS AND THE THREE-COMPARTMENT LUNG MODEL

Meanwhile a three-compartment model devised in the mid twentieth century[14] is still in use, with no need for Fi_{O_2} switching or inert gas infusions. The trade-off is that because the model is overly simplistic it has poor predictive capacity in many respiratory disorders. The three compartments are:

1. The ideal compartment, consisting of alveoli with perfectly matched perfusion and ventilation ($V/Q=1$)
2. The venous admixture or shunt compartment, containing perfused non-ventilated alveoli ($V/Q=0$)
3. The alveolar dead space compartment, consisting of ventilated non-perfused alveoli ($V/Q=\infty$).

The alveolar P_{O_2} in the ideal compartment (PA_{O_2}) is calculated from the alveolar gas equation:

$$PA_{O_2} = -(1 - Fi_{O_2} \times (1 - R)) \times Pa_{CO_2}/R \qquad (18.2)$$

where R is the respiratory exchange ratio, either measured by indirect calorimetry or assumed to be 0.8. Pi_{O_2} is calculated as in Equation 18.1. Pa_{CO_2} is arterial P_{CO_2}.

Most clinicians use the following approximation:

$$PA_{O_2} = Pi_{O_2} - Pa_{CO_2}/0.8$$

It is important to remember that PA_{O_2} is derived from a non-physiological three-compartment lung model. Parameters such as the A–a gradient and venous admixture that are also based on the model (see below) must be regarded in the same light.

TRANSFER FROM ALVEOLI TO ARTERIAL BLOOD (PULMONARY OXYGEN TRANSFER)

The MIGET technique has identified V/Q mismatch and intrapulmonary right-to-left shunt as the two main

causes of reduced pulmonary oxygen transfer in critical illness.[15] Intrapulmonary shunt predominates in the acute respiratory distress syndrome (ARDS), lobar pneumonia and after cardiopulmonary bypass, whereas V/Q mismatch without shunt is more prominent in chronic lung disease.[16]

BEDSIDE INDICES OF PULMONARY OXYGEN TRANSFER

These are either tension based or content based.

TENSION-BASED INDICES

A–a gradient

The A–a gradient is calculated as $PA_{O_2}-Pa_{O_2}$, where PA_{O_2} is the 'ideal' compartment alveolar P_{O_2} determined from the alveolar gas equation (Equation 18.2). Hypoxaemia can then be classified under two headings:

Normal A–a gradient

1. Alveolar hypoventilation (elevated PA_{CO_2})
2. Low Pi_{O_2} ($Fi_{O_2}<0.21$, or barometric pressure <760 mmHg (99 kPa)).

Raised A–a gradient

1. Diffusion defect (rare)
2. V/Q mismatch
3. Right-to-left shunt (intrapulmonary or cardiac)
4. Increased oxygen extraction ($Ca_{O_2}-Cv_{O_2}$).

Although the A–a gradient is a component of the APACHE II, III and IV scoring systems,[17,18] several drawbacks limit its clinical usefulness. They include:

1. Normal values that vary with Fi_{O_2} and age. The normal A–a gradient breathing air is 7 mmHg (0.91 kPa) in young adults and 14 mmHg (1.82 kPa) in the elderly. On 100% oxygen, these values become 31 mmHg (4 kPa) and 56 mmHg (7.3 kPa) respectively.
2. An exaggerated Fi_{O_2} dependence in intrapulmonary shunt (**Fig. 18.1**) and even more so in V/Q mismatch (**Fig. 18. 2**).[19,20]

Pa_{O_2}/Fi_{O_2} ratio

The Pa_{O_2}/Fi_{O_2} ratio is used to define acute lung injury and ARDS,[21] and is an input variable in SAPS II and III,[22] SOFA,[23] APACHE IV[18] and lung injury scoring systems.[24] At sea level its normal value is ≥500 mmHg (65 kPa). In acute lung injury, $Pa_{O_2}/Fi_{O_2}<300$ mmHg (39 kPa), whilst in ARDS the ratio is <200 mmHg (26 kPa).

Its main advantage is simplicity. There are several disadvantages:

1. Barometric pressure alters the normal Pa_{O_2}/Fi_{O_2} ratio. For a young adult breathing air, a ratio of

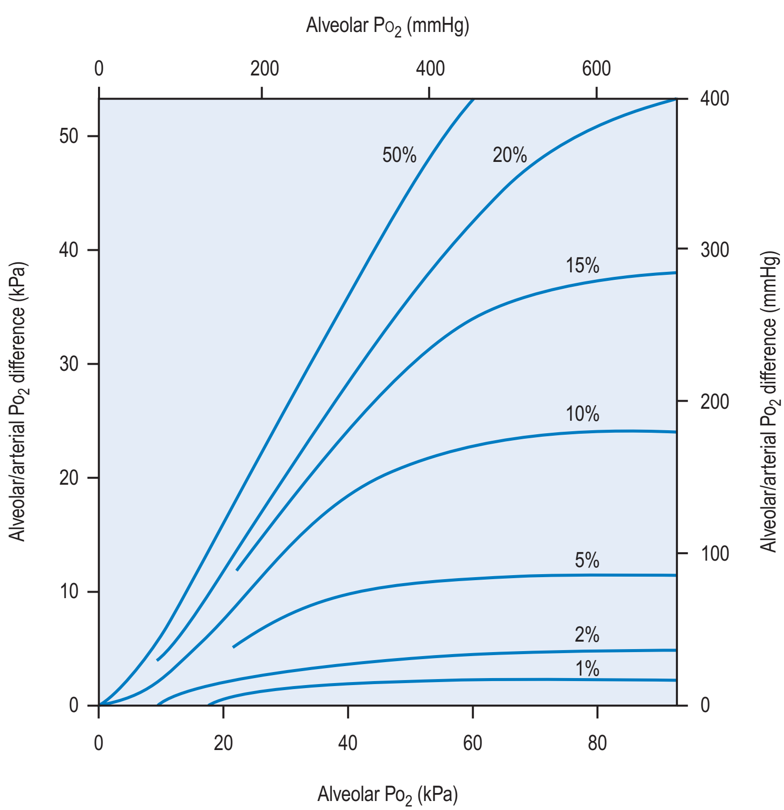

Figure 18.1 Effect of varying Fi_{O_2} (PA_{O_2}) on A–a gradient with different degrees of intrapulmonary shunt. *(Reproduced with permission from Nunn JF. Oxygen. In: Nunn JF, editor. Applied Respiratory Physiology. 4th edn. Oxford, UK: Butterworth-Heinemann; 1993. p. 264.)*

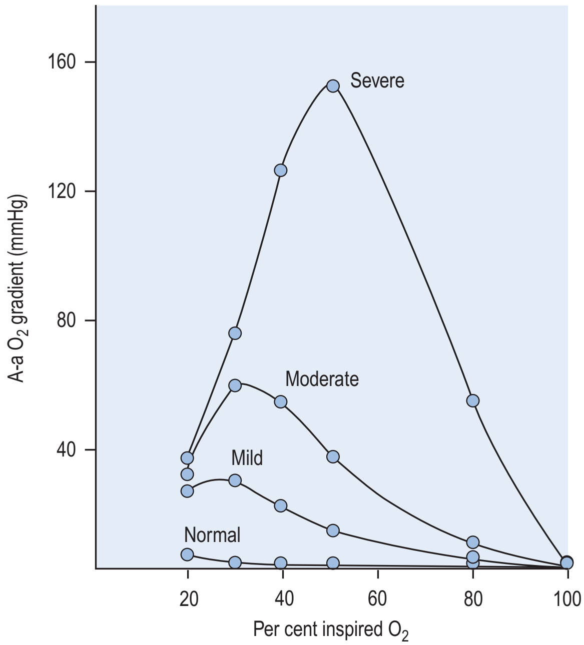

Figure 18.2 Effect of varying Fi_{O_2} on A–a gradient with mild, moderate and severe V/Q mismatch. No allowance is made for absorption atelectasis or alterations in hypoxic pulmonary vasoconstriction. *(Reproduced with permission from D'Alonzo GE, Dantzker DR. Respiratory failure, mechanisms of abnormal gas exchange, and oxygen delivery. Med Clin North Am 1983;67:557–71.)*

380 mmHg (49.4 kPa) is unremarkable at 1600 metres elevation, but not at sea level.

2. Unlike the A–a gradient, the Pa_{O_2}/Fi_{O_2} ratio cannot distinguish hypoxaemia due to alveolar hypoventilation from other causes.
3. The ratio is markedly Fi_{O_2} dependent, both in right-to-left shunt (the predominant ARDS abnormality) and in lungs with a wide V/Q scatter (COPD).[19,20]
4. The ratio is also highly dependent on $Ca_{O_2}-Cv_{O_2}$,[20] which tends to fluctuate markedly in sepsis.

CONTENT-BASED INDICES

Venous admixture (Qs/Qt)

Venous admixture is another construct based on the three-compartment lung model (see above). It represents the proportion of mixed venous blood flowing through the shunt ($V/Q=0$) compartment. It is determined according to the formula:

$$\frac{\dot{Q}_S}{\dot{Q}_T} = \frac{Cc'O_2 - Ca_{O_2}}{Cc'O_2 - C\bar{v}_{O_2}} \tag{18.3}$$

where Cc_{O_2}, Ca_{O_2} and Cv_{O_2} are the oxygen contents of pulmonary end-capillary, arterial and mixed venous blood respectively. Ca_{O_2} and Cv_{O_2} are calculated using data from arterial and mixed venous blood gas analysis and CO-oximetry (**Table 18.1**). Cc_{O_2} must be derived differently, since pulmonary end-capillary blood cannot be sampled. Pc_{O_2} is assumed to equal PA_{O_2} as derived from the alveolar gas equation (Equation 18.2). Sc_{O_2}

Table 18.1 Oxygen dynamics – measured and derived indices

PARAMETER	ABBREVIATION	FORMULA	NORMAL RANGE	UNITS
Functional haemoglobin concentration	$[Hb_{funct}]$	$[Hb_{O_2}]+[Hb]$	12.0–18.0	g/dL
Arterial oxygen tension	Pa_{O_2}	Measured	95±5 12.5±0,65	mmHg kPa
Mixed venous oxygen tension	Pv_{O_2}	Measured	40±5 5.2±0.65	mmHg kPa
Functional saturation	S_{O_2}	$[Hb_{O_2}]/([Hb_{O_2}]+[Hb])$		
Fractional saturation	FHb_{O_2}	$[Hb_{O_2}]/([Hb_{O_2}]+[Hb]+[COHb]+[MetHb])$		
Arterial functional saturation	Sa_{O_2}		0.97±0.02	
Mixed venous functional saturation	Sv_{O_2}		0.75±0.05	
Blood oxygen content	C_{O_2}	$1.39\times[Hb_{funct}]\times S_{O_2}+0.0031\times P_{O_2}$		mL/dL
Arterial oxygen content	Ca_{O_2}		16–22	mL/dL
Mixed venous oxygen content	Cv_{O_2}		12–17	mL/dL
Cardiac index	CI	CO/BSA	2.5–4.2	L/min/m^2
Oxygen delivery index	$D_{O_2}I$	$CI\times Ca_{O_2}\times 10$	460–650	mL/min/m^2
Oxygen consumption index	$V_{O_2}I$	$CI\times(Ca_{O_2}-Cv_{O_2})\times 10$	96–170	mL/min/m^2
Oxygen extraction ratio	O_2ER	$(Ca_{O_2}-Cv_{O_2})/Ca_{O_2}$ or V_{O_2}/D_{O_2}	0.23–0.32	

Hb_{O_2}=oxyhaemoglobin; Hb=reduced haemoglobin; COHb=carboxyhaemoglobin; MetHb=methaemoglobin, BSA=body surface area.

(normally close to 1) can then be computed from an algorithm for the Hb_{O_2} dissociation curve.[25]

Advantages of venous admixture:

1. Unaffected by barometric pressure
2. Unaffected by alveolar hypoventilation
3. Provided intrapulmonary right-to-left shunt is the dominant pathology (e.g. ARDS), venous admixture is stable across the entire Fi_{O_2} range, despite variations in $Ca_{O_2} - Cv_{O_2}$.[19,26]

Disadvantages of venous admixture:

1. Sampling mixed venous blood requires a PA catheter.
2. In V/Q mismatch without right-to-left shunt, venous admixture varies markedly with Fi_{O_2} and virtually disappears at $Fi_{O_2} > 0.5$ (**Fig. 18.3**). Venous admixture is thus of little use in conditions where the dominant gas exchange abnormality is not intrapulmonary right-to-left shunt, such as COPD.

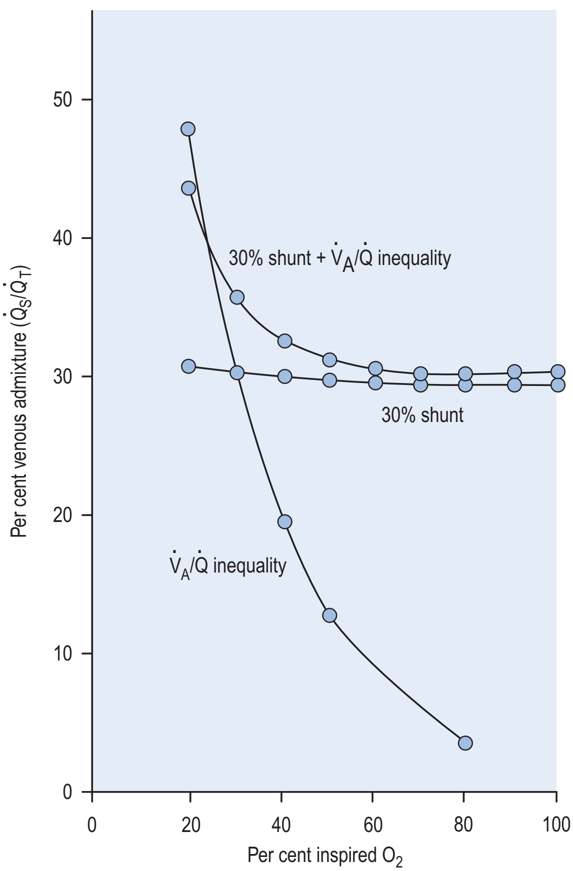

Figure 18.3 Effect of varying Fi_{O_2} on venous admixture in various combinations of V/Q mismatch and shunt. No allowance has been made for absorption atelectasis or alterations in hypoxic pulmonary vasoconstriction. *(Reproduced with permission from D'Alonzo GE, Dantzker DR. Respiratory failure, mechanisms of abnormal gas exchange, and oxygen delivery. Med Clin North Am 1983;67:557–71.)*

When determined at $Fi_{O_2}=1$, venous admixture is an accurate measure of right-to-left shunt. However, exposure to 100% oxygen causes absorption atelectasis of unstable low V/Q units, which increases intrapulmonary shunt.

Estimated shunt fraction

If a fixed $Ca_{O_2} - Cv_{O_2}$ is assigned, no PA catheter is necessary. However, in critical illness $Ca_{O_2} - Cv_{O_2}$ can range from 1.3 mL/dL to 7.4 mL/dL. Hence the inaccuracy from assigning a fixed value is such that even the direction of change of estimated shunt can be wrong.[26]

Non-invasive estimates of V/Q mismatch and shunt

Simpler lung models using varying Fi_{O_2} as a forcing function are discussed above.[11–13]

ARTERIAL BLOOD

Indices of arterial oxygenation are Pa_{O_2} and Sa_{O_2}. They are linked by the Hb_{O_2} dissociation curve (**Fig. 18.4**).

Hypoxaemia is defined as $Pa_{O_2} < 60$ mmHg (7.8 kPa) or $Sa_{O_2} < 0.9$. These values lie near the descending portion of the Hb_{O_2} dissociation curve, so that a further drop in Pa_{O_2} leads to a marked fall in Sa_{O_2} and thus Ca_{O_2}.

BLOOD GAS ANALYSIS AND CO-OXIMETRY

Arterial blood is collected in a purpose-designed syringe containing lyophilised heparin to a final concentration of 20–50 U/mL. Pa_{O_2} measurements are made by a Clark electrode, and Sa_{O_2} by CO-oximetry. The Clark electrode works on polarographic principles,

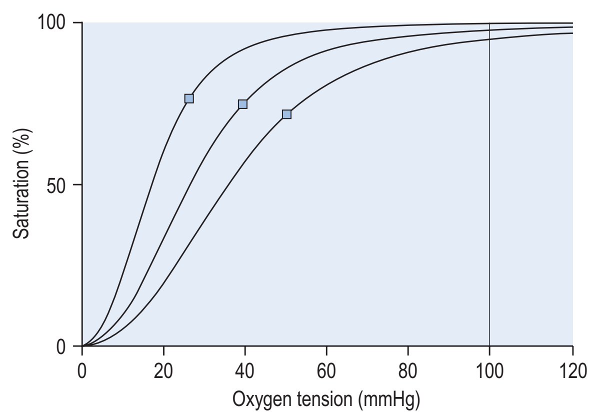

Figure 18.4 Three Hb_{O_2} dissociation curves: normal (P50=26.7 mmHg (3.47 kPa)), left-shifted (P50= 17 mmHg (2.21 kPa)) and right-shifted (P50=36 mmHg (4.68 kPa)). The vertical line represents the normal oxygen loading tension ($P_{O_2}=100$ mmHg (13 kPa)). The filled squares represent an oxygen extraction of 5 mL/dL blood, assuming a haemoglobin concentration of 150 g/L. *(Reproduced with permission from Morgan TJ. The Hb_{O_2} dissociation curve in critical illness. Crit Care Resusc 1999;1:93–100.)*

Table 18.2 Pre-analytic and analytic errors in P_{O_2} measurement

PRE-ANALYTIC	ANALYTIC
Oxygen diffusing into or out of air bubbles along tension gradients	Inter-analyser variability. There is 7–8% measurement variation on the same sample
Contamination with flush solution. Discard volume should be 2–3 times the internal volume of cannula and tubing	Inadequate anticoagulation, allowing protein deposits on electrodes
Pseudohypoxaemia. Oxygen consumption in vitro from extreme leucocytosis	Non-linearity at high P_{O_2} (>150 mmHg (19.5 kPa))
Artefactual Pa_{O_2} elevations. With syringes stored on ice, the semipermeable polypropylene allows oxygen ingress, facilitated by the cold-induced increase in oxygen solubility	Maintenance of electrode temperature within narrow limits (37+/– 0.1°C) is critical. P_{O_2} changes by 7% for every degree Celsius temperature change
	Minimal interference by nitrous oxide and volatile anaesthetic agents unless the polarising voltage of the electrode exceeds 600 mV
	Tonometry is the primary reference method. Quality control materials such as aqueous, perfluorocarbon and bovine haemoglobin solutions are used for convenience
	Arterial blood gas tensions fluctuate breath to breath.[75] Intermittent analysis is a snapshot

and a CO-oximeter computes the concentrations of each of the four main haemoglobin species (Hb_{O_2}, Hb, COHb, MetHb) from light absorbances of haemolysed blood at several wavelengths. Sa_{O_2} is functional saturation, determined from concentrations of Hb_{O_2} and Hb (see Table 18.1). Interference to CO-oximetry arises from substances with competing absorbance spectra, such as bilirubin, HbF, lipid emulsions and intravenous dyes. Increasing the number of wavelengths, for example to 128, can reduce or eliminate interference.

ERRORS

Pre-analytic and analytic errors in P_{O_2} measurement are set out in **Table 18.2**.

TEMPERATURE CORRECTION

All measurements are at 37°C. Temperature-corrected values can be calculated if the core temperature of the patient is entered into the device software. Most clinicians interpret blood gas data at 37°C, except when evaluating the A–a gradient (see Ch. 92, Acid–base balance and disorders).

CONTINUOUS INTRA-ARTERIAL BLOOD GAS MONITORING (Table 18.3)[27]

Multiparameter fibreoptic sensors can be placed in the arterial stream. Fibreoptic sensors are called 'optodes', and those measuring P_{O_2} normally operate by fluorescence quenching. They require calibration with precision gases or solutions before use. Typical sensors are 0.5 mm in diameter, and can be inserted through 20 G arterial cannulae. The 90% in vitro response time to a change in P_{O_2} is 78 seconds. P_{O_2} drift in vivo is 0.03 mmHg/h (0.0039 kPa/h). Recalibration in vivo can be performed against conventional blood gas analysis. Accuracy on in vitro and animal testing is good.

Clinical trials evaluating the accuracy of these monitoring systems have revealed varying degrees of bias and imprecision. Evidence demonstrating an improved outcome when therapeutic decisions are based on data from these devices is lacking. These factors combined with the costs of these devices have limited their bedside application.

Problems encountered with intra-arterial sensors, particularly artefactual due to flow and position, have prompted the development of extracorporeal monitors that can be placed in line but ex vivo. These devices do not provide continuous real-time data. When a measurement is desired, a sample is drawn into the externally located cassette then returned. Results are available in two minutes. In preterm neonates this method can reduce red cell transfusion requirements.[28]

TRANSCUTANEOUS P_{O_2} AND P_{CO_2} MONITORING

Continuous non-invasive assessment of blood gas tensions is possible with transcutaneous P_{O_2} and P_{CO_2} monitoring. Available systems incorporate O_2 and CO_2 electrodes with integral thermistors and servo-controlled heaters. P_{O_2} measurement utilises the principle of the Clark electrode, while the P_{CO_2} device is a pH-sensitive glass electrode. The skin is warmed to

Table 18.3 Continuous intra-arterial Pa_{O_2} monitoring – advantages and disadvantages

ADVANTAGES	DISADVANTAGES
Eliminates pre-analytic errors of intermittent blood gas analysis	The 'wall' effect – a sudden decrease in measured Pa_{O_2} due to contact with the arterial wall, with averaging of arterial and wall oxygen tensions. The problem is reduced in larger arteries such as the femoral artery
More sensitive than pulse oximetry to changes in arterial oxygenation when Pa_{O_2}>70 mmHg (the flat part of the Hb_{O_2} dissociation curve)	The 'flush' effect. Unless the sensor is inserted a sufficient distance beyond the cannula tip, measured Pa_{O_2} can be altered by contamination with the continuous flush solution
Free from the sources of error of pulse oximetry (see Table 18.2)	Damping of the arterial waveform
Near-real-time Pa_{O_2} allows prompt tracking of responses to changed ventilator settings	Large footprint of the free-standing monitor
Reduced exposure of personnel to potentially infected blood	
Reduced blood loss for diagnostic purposes	

42–44°C to achieve good correlation with arterial values. Transcutaneous monitors generate reliable P_{CO_2} values provided perfusion is unimpaired, but P_{O_2} measurements are more for trend analysis. Skin warming necessitates frequent site changes to prevent burns, and there is a need for regular recalibration. Monitoring is not recommended in haemodynamically unstable patients.

Transcutaneous monitors have a role in the prevention of neonatal hyperoxia, which is not reliably detected by pulse oximetry.[29] They may also have a role in the detection of sleep apnoea and hypoventilation syndromes, and for monitoring during nocturnal non-invasive ventilation.[30]

PULSE OXIMETRY[31,32]

Pulse oximetry determines Sp_{O_2} from the absorbance of light at wavelengths 660 nm (red) and 940 nm (infra-red) by tissue capillary beds such as fingers, forehead, earlobes and the nasal septum. Two light-emitting diodes cycle on and off at multiples of the mains frequency. A single photodiode detects the transmitted light, and applies a correction for background ambient light. The emergent signal is pulsatile due to arterial volume fluctuations. Subtraction of the background signal (tissue, capillary blood and venous blood) isolates the arterial component.

For both wavelengths, absorbance (A) is determined as follows:

$$A = \log_{10}(I_0 / I)$$

where I_0=incident light intensity and I=emergent light intensity. For a given chromophore, A is proportional to its concentration (Beer's law) and to the path length (Lambert's law). From the pulsatile (AC) and background (DC) absorbance signals at both wavelengths, a ratio (R) is derived:

$$R = (AC_{660} / DC_{660}) / (AC_{940} / DC_{940})$$

Sp_{O_2} is then computed from R, using software 'look-up' tables of empirically derived relationships between R values and either Sa_{O_2} or FHb_{O_2} measured in the arterial blood of volunteers breathing hypoxic gas mixtures.

Sp_{O_2} is usually displayed as a percentage. Since the signal is derived from two wavelengths there is an inherent incorrect assumption that Hb_{O_2} and Hb are the only haemoglobin species in the light path. However, with normal dyshaemoglobin concentrations the error is trivial. Some manufacturers calibrate R against FHb_{O_2} (fractional saturation) rather than Sa_{O_2} (functional saturation). Provided volunteers generating the data have normal dyshaemoglobin concentrations, differences between the two calibrations are small.

SPEED OF RESPONSE

Sp_{O_2} is averaged over 3–6 seconds, and updated every 0.5–1 second. With forehead probes a sudden reduction in Fi_{O_2} produces a response within 10–15 seconds, whereas with finger probes and peripheral vasoconstriction the delay can exceed 1 minute.

ACCURACY

In the 90–97% saturation range, Sp_{O_2} has a mean absolute bias of <1%, and a precision (SD of bias) of <3%. At Sa_{O_2}<0.8 there is significant imprecision and a tendency towards negative bias. This is because very low Sa_{O_2} values are unsafe in volunteers, necessitating extrapolation from Sp_{O_2}/R relationships at higher saturations.

ERROR

Causes of error are set out in **Table 18.4**. A falsely high Sp_{O_2} is of greatest concern.

Unlike CO-oximetry, pulse oximetry is not subject to interference from bilirubin, lipid emulsions and HbF.

Table 18.4 Causes of error in Sp_{O_2} readings

FACTOR	COMMENT
COHb	Measured as Hb_{O_2} – Sp_{O_2} may be falsely high – see text
MetHb	Absorbs both wavelengths – see text
Low saturations	Progressive inaccuracy below 70–80%, usually falsely low Sp_{O_2}
Prominent venous signal	Dependent limb, tricuspid regurgitation (venous pulsations) – falsely low Sp_{O_2}
Non-pulsatile flow	Cardiopulmonary bypass – poor signal
Vasoconstriction, limb ischaemia, shock states	Low pulsatile signal
Motion artefact	Tremor, voluntary movement – falsely low Sp_{O_2}
Ambient light	Strong sunlight, fluorescent and xenon lamps, flickering light– falsely low Sp_{O_2}
Anaemia	No effect
Dyes	Methylene blue, indocyanine green, indigo carmine – falsely low Sp_{O_2}
Black skin pigmentation	Variable precision and bias. May require separate calibration
Nail polish	Especially blue. Falsely low Sp_{O_2}. Acrylic nails do not interfere
Optical shunting	Due to inadequate probe contact – falsely low Sp_{O_2}
Radio-frequency interference	Reported with MRI scanners – falsely high Sp_{O_2}

Dyshaemoglobins and pulse oximetry

Pulse oximeters cannot distinguish COHb from Hb_{O_2}. When [COHb] is elevated, Sp_{O_2} tends to overestimate Sa_{O_2}. Sp_{O_2} can thus provide false reassurance when hypoxaemia is combined with a high [COHb], for example after an inhalational burn injury.

MetHb has more complex effects, since it absorbs both wavelengths. At normal saturations, increased [MetHb] causes underestimation of Sa_{O_2}, but at very low oxygen tensions overestimation is possible. At [MetHb]≥35%, the R value becomes unity, which translates to Sp_{O_2}=85%.

IMPORTANCE OF PULSE OXIMETRY

Pulse oximeters generate accurate real-time information without calibration, within moments of sensor placement. They are mandatory in patient transport, and in high-acuity areas such as operating rooms, recovery rooms and intensive care units. They are also useful screening tools. On the down side, pulse oximeters are insensitive to changes in arterial oxygenation at higher Pa_{O_2} values (>70–100 mmHg (9.1–13 kPa)). They are also the most common source of false alarms in intensive care.

PULSE CO-OXIMETRY[33,34]

Additional continuous real-time non-invasive monitoring of absolute total haemoglobin concentrations and trends becomes possible with these multiwavelength devices. Accuracy remains acceptable in low perfusion states and in patients requiring vasopressor support.

MONITORING HAEMOGLOBIN–OXYGEN AFFINITY

Haemoglobin–oxygen affinity is the relationship between the oxygen tension of blood and its oxygen content, described by the sigmoid-shaped Hb_{O_2} dissociation curve (see Fig. 18.4). The P50 is the oxygen tension at S_{O_2}=0.5. The normal value in humans is 26.7 mmHg (3.47 kPa). Factors that decrease haemoglobin–oxygen affinity increase the P50. They include acidaemia (the Bohr effect), hypercarbia, increased erythrocytic 2,3-DPG and fever, whereas P50 is decreased (increased affinity) by alkalaemia, hypocarbia, low 2,3-DPG concentrations, hypothermia, COHb, MetHb and FHb.

In the intensive care unit, it is possible to calculate accurate P50 values from a single measurement of blood gases and Sa_{O_2} up to Sa_{O_2}=0.97. However, the impact of haemoglobin–oxygen affinity on tissue oxygenation in critical illness appears to be small,[35,36] making routine monitoring unnecessary.

OXYGEN DYNAMICS

Common indices of oxygen dynamics are set out in Table 18.1.

D_{O_2}/V_{O_2} RELATIONSHIPS

Nearly 40 years ago an association was reported between hyperdynamic oxygen flow patterns and survival after high-risk non-cardiac surgery.[37] This led to

the concept that maintaining an induced perioperative hyperdynamic state to prevent an acquired oxygen debt might be protective. Although supported at a single-centre level, this hypothesis was not validated by large multicentre studies.[38,39] In fact, aggressive pursuit of hyperdynamic goals seemed counterproductive for the broad ICU population.[40]

Common therapeutic goals were $CI > 4.5$ L/min/m^2, $D_{O_2}I > 600$ mL/min/m^2, $\dot{V}_{O_2}I > 170$ mL/min/m^2. However the $V_{O_2}I$ target was especially difficult to achieve. The focus subsequently narrowed to the $D_{O_2}I$ target alone, which removed the need for PA catheterisation. On this basis there is better emerging evidence of benefit in high-risk surgery,[41–43] although definitive multicentre confirmation is awaited.

MEASURING $D_{O_2}I$

Although $D_{O_2}I$ determinations require accurate measurements of CI and Ca_{O_2}, a PA catheter is not essential (see Ch.16). Normal ranges can be quoted (see Table 18.1), but oxygen demand in critical illness is so variable that isolated $D_{O_2}I$ measurements are difficult to interpret.

MEASURING $V_{O_2}I$

The two methods of measuring $V_{O_2}I$ are the reverse Fick method (see Table 18.1), and indirect calorimetry.

Reverse Fick method

The reverse Fick method requires a PA catheter, and has large random errors ranging from 17% overestimation to 13% underestimation. Changes cannot be detected reliably unless they exceed 20%. The error is increased by lung inflammation, when up to 20% of $V_{O_2}I$ can arise from the lungs alone.

Indirect calorimetry

Indirect calorimetry has better accuracy. $V_{O_2}I$ is determined from the volumes and oxygen concentrations of inspired and expired gas. However, high Fi_{O_2} settings introduce error. Newer devices retain accuracy up to $Fi_{O_2}=0.8$, with relative errors of <5%.

MIXED VENOUS BLOOD

Mixed venous sampling is by gentle aspiration of blood from the distal port of an unwedged PA catheter to ensure complete admixture of blood from superior and inferior venae cavae and coronary sinus. Mixed venous O_2 and CO_2 tensions and content are flow-weighted averages of the venous effluents of multiple tissues. As such they can fail to detect pockets of hypoxia and hypercarbia.

MIXED VENOUS P_{O_2} (Pv_{O_2})

Venous gas tensions reflect post-capillary and tissue gas tensions. A Pv_{O_2} below 26 mmHg (3.38 kPa) is suggestive of cellular hypoxia.[44] Paradoxically, a normal or high Pv_{O_2} does not exclude regional tissue hypoxia, whether cytopathic[45] or as a result of tissue shunting.[46]

MIXED VENOUS OXYGEN SATURATION (Sv_{O_2})[47]

Sv_{O_2} is measured either intermittently by CO-oximetry on mixed venous samples or continuously by fibreoptic reflectance oximetry using a modified PA catheter. Sv_{O_2} measurements have a number of potential uses:

1. To calculate Cv_{O_2} (see Table 18.1). Cv_{O_2} can then be used to determine Qs/Qt, $V_{O_2}I$ by the reverse Fick method, the oxygen extraction ratio (Table 18.1), and cardiac output by the Fick method.
2. As an indirect index of tissue hypoxia. A Sv_{O_2} value of 0.5 corresponds to the theoretical critical Pv_{O_2} of 26 mmHg (3.38 kPa). Values between 0.7 and 0.8 represent a desirable balance between global oxygen supply and demand (see Table 18.1), with lactic acidosis appearing between 0.3 and 0.5.[47] Values exceeding 0.8 can be seen in high-flow states such as sepsis, hyperthyroidism and severe liver disease.

Sv_{O_2} as a therapeutic target (≥0.7) failed to improve survival in a multicentre trial.[48] Only two-thirds of the treatment group achieved the target. Like Pv_{O_2}, Sv_{O_2} is insensitive to cytopathic hypoxia and tissue shunting. In chronic heart failure, low values are surprisingly well tolerated.

CENTRAL VENOUS SATURATION (Scv_{O_2})[47]

As with Sv_{O_2}, Scv_{O_2} can be measured either continuously using a central venous catheter modified for reflectance oximetry, or by intermittent sampling and CO-oximetry. Scv_{O_2} is normally 2–3% lower than Sv_{O_2}. However, in shock this difference can be reversed. Trends in Sv_{O_2} and Scv_{O_2} in response to management usually run in parallel.

In the Rivers single-centre study of early intervention in the hypodynamic phase of severe sepsis and septic shock,[49] resuscitation was directed at a Scv_{O_2} target of >0.7, along with specific central venous pressure and mean arterial pressure goals and an aggressive transfusion policy. There were reductions in 28- and 60-day mortality and in the duration of hospitalisation compared with standard treatment. A target of $Scv_{O_2} \geq 0.7$ now has equal billing with $Sv_{O_2} \geq 0.65$ in the management guidelines of the Surviving Sepsis Campaign.[50] It is unclear whether intermittent sampling can be substituted with equivalent benefit.

In a subsequent multicentre study with a protocol similar to that of the Rivers study, 10% venous lactate clearance was at least equivalent (non-inferior) to Scv_{O_2} as a therapeutic target in severe sepsis and septic shock.[51] Furthermore, judging by the low take-up in Australia and New Zealand[52] clinicians still question whether the Rivers findings can be generalised to the wider emergency and critical care septic population.[53] This is the subject of a multicentre trial (Australasian Resuscitation in Sepsis Evaluation Randomised

Controlled Trial; ARISE-RCT; ClinicalTrials.gov Identifier: NCT 00975793).

MIXED VENOUS–ARTERIAL P_{CO_2} GRADIENT (ΔP_{CO_2})

ΔP_{CO_2} (normally about 6 mmHg (0.78 kPa)) is markedly increased during cardiac arrest and in experimental low-output states, but lacks sensitivity and specificity as a global index of tissue hypoxia. A sudden increase in the respiratory quotient (V_{CO_2}/V_{O_2}), or in the venoarterial CO_2 tension difference/arteriovenous O_2 content difference to >1.4[54] may be more reliable markers of the onset of anaerobic metabolism. The central venous–arterial P_{CO_2} gradient appears to behave similarly to ΔP_{CO_2} as an index of reduced tissue perfusion.[55]

PLASMA LACTATE AND REDOX INDICES

See Chapter 19.

REGIONAL OXYGENATION INDICES

REGIONAL P_{CO_2}[56]

Regional P_{CO_2} reflects the balance between arterial blood CO_2 content, tissue blood flow and tissue CO_2 production. The CO_2 gap, which is regional $P_{CO_2} - Pa_{CO_2}$, was devised to correct regional P_{CO_2} for varying arterial CO_2 content. As tissue blood flow falls, reduced CO_2 clearance causes the CO_2 gap to increase. With the onset of anaerobic metabolism, tissue CO_2 production steadily decreases, although regional metabolic acidosis generates some CO_2 by proton titration of tissue and capillary HCO_3^-. A rising CO_2 gap signals falling tissue blood flow. It cannot identify the onset of anaerobic metabolism.[57]

GASTRIC TONOMETRY

Gastric tonometry was developed in the knowledge that splanchnic hypoperfusion occurs early in circulatory shock, tends to persist as 'covert shock', and is manifested by intramucosal hypercarbia and acidosis. A gastric tonometer was developed as a modified nasogastric tube with a silicone balloon 11.4 cm from the tip. Gastric mucosal CO_2 equilibrates with luminal CO_2, which equilibrates with (and is measured in) fluid filling the balloon. Early on, this fluid was saline. Subsequently air was found to have more rapid equilibration characteristics.

The original method involved calculation of intramucosal pH (pHi) by substituting gastric luminal P_{CO_2} and arterial [HCO_3^-] in the Henderson–Hasselbalch equation. Intramucosal acidosis was defined as pHi < 7.3 and taken to indicate inadequate splanchnic perfusion. However, although pHi can reflect shock severity, it has been difficult to demonstrate its value as a therapeutic target.[58] Changing the monitoring end-point from pHi to the mucosal–arterial CO_2 gap (normally 8–10 mmHg (1.04–1.3 kPa)) has removed the most fundamental flaw: the use of arterial [HCO_3^-] as a surrogate for mucosal [HCO_3^-]. The gastric CO_2 gap derived from air tonometry is an independent prognostic factor in critical illness.[59] Simultaneous end-tidal CO_2 measurement allows the regular calculation of a gastric to end-tidal CO_2 gap, a parameter linked to outcome in high-risk surgery.[60]

Despite these improvements, the technique has not found widespread application. There have been several barriers:

1. The need for a nasogastric tube
2. Signal degradation by luminal contents, including feeds and blood; feeds must be stopped 2 hours prior to measurements, jeopardising nutritional support
3. Inability to identify a clear hypoxic threshold; empirical recommendations have been to target a CO_2 gap <25 mmHg (3.25 kPa)
4. A need to suppress gastric acidity to prevent luminal CO_2 generation by HCl titration of duodenal bicarbonate
5. A lack of convincing evidence that tonometry-guided therapy improves outcome.[58,61]

SUBLINGUAL CAPNOMETRY[56]

Measurement of the sublingual interstitial CO_2 tension has the advantage of accessibility with minimal invasion. Optode sensors provide the most rapid response. As with all tissues, sublingual P_{CO_2} is best combined with Pa_{CO_2} to generate the sublingual CO_2 gap, which tracks sublingual microcirculatory blood flow.[62] The sublingual CO_2 gap has predicted outcome better than lactate or Sv_{O_2} in a limited number of shocked patients. It remains to be seen whether the technique can be used to guide therapy.

More recently earlobe P_{CO_2} has shown similar potential.[63]

CEREBROVENOUS OXYGEN SATURATION MONITORING

See Chapter 75.

DIRECT TISSUE P_{O_2} MEASUREMENT

Measurements have been recorded primarily in animal models in the brain, subcutaneous tissue, muscle and renal beds under a variety of perfusion insults. Tensions are commonly around 30–45 mmHg (3.9–5.85 kPa), but can range from <10 mmHg (1.3 kPa) in the renal medulla to >70 mmHg (9.1 kPa) in subcutaneous tissue. In patients this is largely impractical, although in vivo magnetic resonance imaging is one possible future approach.[64]

OTHER REGIONAL TECHNIQUES

DYNAMIC MICROCIRCULATORY IMAGING

Orthogonal polarisation spectroscopy (OPS) and sidestream dark field (SDF) imaging allow real-time

quantification of microvascular flow via derived indices such as the 'functional capillary density' and 'mean flow index'.[65] The tissue bed most commonly evaluated in intensive care has been the sublingual circulation, but rectal, oral, ileal (via stoma) and other microcirculations can be visualised. The rationale is an extension of the covert or compensated shock concept as originally applied to gastric tonometry, in which multiple organ dysfunction is driven by subtle microcirculatory compromise causing an ongoing tissue oxygen deficit despite acceptable macrocirculatory parameters.[66] Of some concern, the relationship between sublingual and intestinal microcirculations may not be reliably consistent, for example in early abdominal sepsis.[67]

NEAR-INFRARED SPECTROSCOPY (NIRS) WITH FUNCTIONAL OCCLUSION TEST[68]

NIRS uses the differential absorbance properties of Hb_{O_2} and Hb in muscle vessels with diameter <1 mm (arterioles, venules and capillaries) subjected to light of wavelengths 680–800 nm. Light at these wavelengths penetrates >1 cm below the skin, but 95% of the detected signal is from tissue <2.4 mm in depth. The thenar eminence is normally selected for its reliable low subcutaneous thickness at any body mass index and its amenability to induced proximal vascular occlusion via a blood pressure cuff. Device software calculates three main parameters; tissue haemoglobin saturation (St_{O_2}), total tissue haemoglobin (TTH) and absolute tissue haemoglobin index (THI). Preliminary data from patients with septic shock suggest that the thenar eminence and knee area tissue oxygen saturation may be predictive of mortality; however, these variables were not superior to arterial lactate in their predictive ability.[69,70]

The functional occlusion test is designed to detect subtle microcirculatory dysfunction, which may be present in covert shock despite unremarkable resting St_{O_2} values. The sphygmomanometer cuff is inflated >30 mmHg (3.9 kPa) above systolic pressure either for 3 minutes or until St_{O_2} stabilises at 40%,[71] then released. The St_{O_2} desaturation slope ($RdecSt_{O_2}$) during occlusion is an indirect index of muscle V_{O_2} (reduced in sepsis and shock states). On cuff release the resaturation slope ($RincSt_{O_2}$) coupled with the degree of St_{O_2} overshoot (ΔSt_{O_2}) and the THI increment due to the associated reactive hyperaemia quantify reperfusion dynamics and vascular recruitment. These are also decreased in sepsis and shock states (**Fig. 18.5**).

Other regional techniques showing some promise include use of the pulse oximeter plethysmographic curve as a means of monitoring the microcirculation (as well as macrocirculatory fluid responsiveness)[72] and optical spectroscopy.[73]

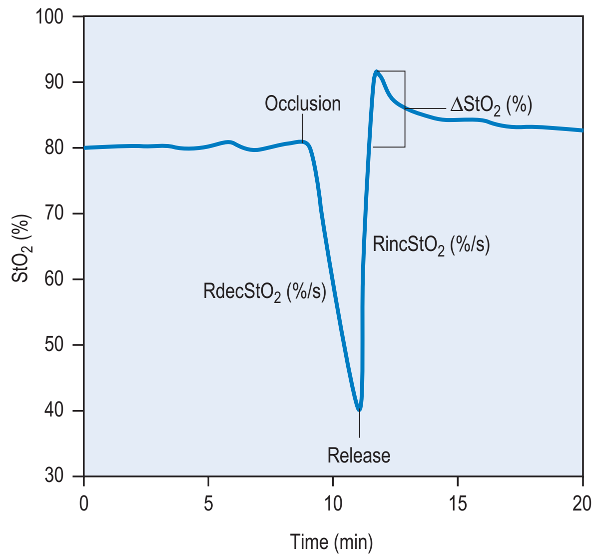

Figure 18.5 Schematic representation of a St_{O_2} curve measured at the thenar eminence during a functional occlusion test. At the point marked 'occlusion' the sphygmomanometer cuff is inflated >30 mmHg (3.9 kPa) above systolic pressure and released when $St_{O_2} \leq 40\%$. The desaturation slope ($Rdec\ St_{O_2}$) reflects muscle V_{O_2}, and the resaturation slope ($RincSt_{O_2}$) and saturation overshoot (ΔSt_{O_2}) quantify reperfusion dynamics and vascular recruitment. All tend to decrease in sepsis and shock states.

THE PROBLEM OF TISSUE HETEROGENEITY

Despite the emerging human data concerning tissue oxygenation, several areas of uncertainty remain due to the microcirculatory heterogeneity of different tissue beds. There are important differences in both the magnitude and direction of response to a hypoxic or a hypotensive insult.[74] Consequently, identification of a dysoxic threshold in individual tissues remains difficult. More precise knowledge of these variables should eventually provide clinicians with practical resuscitation end-points in hypoxia and shock and may facilitate the practice of 'permissive hypoxia', but at present titration of therapy based on monitoring of tissue oxygenation remains an elusive goal.

Lactic acidosis

D James Cooper, Alisa M Higgins and Alistair D Nichol

Lactic acidosis is a metabolic disorder commonly observed in critically ill patients, although the precise prevalence is unknown. The definition of lactic acidosis varies in the literature, although conventionally it is defined as the combination of a blood lactate concentration greater than 5 mmol/L and an arterial blood pH of less than 7.35.[1,2] It has been recognised, however, that the presence of hypoalbuminaemia may mask an anion gap and further that concomitant metabolic or respiratory alkalosis may raise the pH. Lactic acidosis is caused by overproduction of lactate, decreased lactate metabolism, or a combination of the two.

Lactic acidosis in critically ill patients is associated with a high mortality rate,[3] as high as 83%.[1] Lactic acidosis has been associated with higher mortality than other types of acidosis,[3] and increasing blood lactate concentrations have been shown to be associated with increased mortality.[1,4,5] In over 1000 patients with a primary or secondary diagnosis of infection an initial lactate of ≥4 mmol/L was associated with sixfold higher odds of acute-phase death, and acute-phase and in-hospital deaths increased linearly with lactate.[4] However, in 126 patients with severe sepsis or septic shock, lactic acidosis but not hyperlactaemia alone was found to predict in-hospital mortality more exactly.[6] Lactate clearance is also associated with mortality. In 111 patients with severe sepsis, a higher lactate clearance at 6 hours was associated with a decreased mortality rate.[7] Similarly, surgical ICU patients had an increased mortality when the time to normalise lactate levels was greater than 48 hours, with a significantly greater mortality (67% and 100%) when lactate levels failed to normalise.[8,9] In an individual patient, however, prognosis is always dependent on the underlying condition, the initial degree of lactic acidosis being a clinically useful indicator of shock severity, and serial assessment allowing evaluation of overall response to therapy. Recently, blood lactate concentration has been identified as one marker of the degree of shock triggering treatment in septic patients who may benefit from early goal-directed therapy.[10]

Understanding the clinical significance of lactic acidosis is assisted by the knowledge that in healthy athletes very severe but short-lived lactic acidosis during exercise is harmless and insignificant.

PATHOPHYSIOLOGY

There is a continuous cycle of lactate production and metabolism. Lactate is a metabolic end-product of anaerobic glycolysis and is produced by the reduction of pyruvate in a reaction catalysed by lactate dehydrogenase (LDH):

$$\text{pyruvate} + \text{NADH} + \text{H}^+ \xleftrightarrow{\text{LDH}} \text{lactate} + \text{NAD}^+$$

Lactate is produced at about 0.8 mmol/kg per hour, mainly in skeletal muscle, skin, brain, intestine and red blood cells.[11] In critically ill patients, lactate production occurs in many other tissues including lung and liver. Lactate clearance occurs primarily in the liver, with an important contribution from the kidneys, but it can occur to a lesser extent in other organs such as skeletal muscle.[12] Blood lactate levels are normally less than 2 mmol/L and lactic acidosis occurs when lactate production exceeds metabolic capacity, or when the latter is decreased by organ dysfunction. The liver has a key role in lactate homeostasis and many patients who develop lactic acidosis have decreased metabolic capacity due to liver disease.[13]

Lactate formation is dependent upon pyruvate that is produced primarily from the metabolism of glucose by glycolysis, the rate of which is controlled by three unidirectional enzymes and the activity of one of these is increased by increasing intracellular pH. Acidosis therefore decreases (and alkalosis increases) glycolysis and pyruvate, and consequently also lactate production. When oxygen is available, pyruvate enters the mitochondria and is oxidised and lactate does not accumulate. During this process, 36 molecules of adenosine triphosphate (ATP) are produced. Under conditions of hypoxia, pyruvate is unable to enter the mitochondria and is converted to lactate instead. This process generates 2 molecules of ATP; therefore, energy production continues (at a reduced rate) under anaerobic conditions.

In critically ill patients, lactic acidosis is often due to shock. In cardiogenic and hypovolaemic shock, hypoperfusion and tissue hypoxia increase lactic acid production, whereas decreased hepatic perfusion decreases lactic acid metabolism. In septic shock, lactic acidosis is

multifactorial and hypoperfusion contributes to it, by microvascular disruption causing regional hypoperfusion and by impaired mitochondrial cellular oxygen utilisation.

CLASSIFICATION OF LACTIC ACIDOSIS

The Cohen & Woods classification of lactic acidosis defines two subgroups of lactic acidosis depending on the presence (type A) or absence (type B) of tissue hypoxia (**Table 19.1**).[14] Type A due to tissue hypoxia is common in critically ill patients, although clinically most patients have features of both type A and type B lactic acidosis, with increased lactate formation from tissue hypoxia and decreased lactate clearance occurring together. Tissue hypoxia is most commonly due to hypoperfusion occurring due to shock (septic, cardiogenic or hypovolaemic), hypotension, cardiac arrest, acute heart failure, or regional hypoperfusion (in particular, mesenteric ischaemia), although it may also be due to reduced tissue oxygen delivery or utilisation due to very severe hypoxaemia, very severe anaemia or carbon monoxide poisoning. Type B lactic acidosis is subdivided into B1 (lactic acidosis occurring in association with an underlying disease), B2 (lactic acidosis due to drugs or toxins), and B3 (lactic acidosis due to inborn errors of metabolism).

Table 19.1 Classification of lactic acidosis

Type A	Shock Very severe hypoxaemia Very severe anaemia Carbon monoxide poisoning
Type B1 (underlying disease)	Sepsis Liver failure Thiamine deficiency Malignancy Phaeochromocytoma Diabetes
Type B2 (drug or toxin)	Epinephrine (adrenaline) Salbutamol Propofol Nucleoside analogue reverse transcriptase inhibitor Ethanol Methanol Paracetamol Nitroprusside Salicylates Ethylene (and propylene) glycol Biguanides Fructose Sorbitol Xylitol Cyanide Isoniazid
Type B3 (rare inborn errors of metabolism)	Glucose-6-phosphatase deficiency Fructose-1,6 diphosphatase deficiency Pyruvate carboxylase deficiency Deficiency of enzymes of oxidative phosphorylation

SEPSIS

There has been much debate[15] whether the hyperlactaemia of sepsis results from net increased cellular production[16] or reduced net clearance.[17] It is likely that, in such patients, the cause of lactic acidosis is multifactorial. As these patients are often haemodynamically unstable, lactate production can increase as a result of inadequate oxygen delivery from hypoperfusion. Other mechanisms thought to contribute to development of lactic acidosis in sepsis include increased pyruvate production,[18] release of lactate from lung parenchyma,[19,20] decreased pyruvate dehydrogenase (PDH) activity,[21,22] and reduced clearance of lactate.[23,24]

Tissue hypoxia may not be a major mechanism for regional lactate production during sepsis: hyperlactaemia is thought to be linked to the severity of the septic cellular inflammatory response and hypermetabolic state.[15,25] Net lactate production from the hepatosplanchnic bed is uncommon in septic patients[26] and nuclear magnetic resonance spectroscopy suggests that hyperlactaemia may occur without tissue hypoxia.[27]

LUNG INJURY

The lung is a primary source of lactate production in patients with ARDS, pulmonary release of lactate being directly related to the severity of lung injury,[20,28] supporting the view that the primary contributors are the tissues with the most inflammation or injury. The increased lactate production by the injured lung is not only secondary to anaerobic metabolism in the hypoxic regions of the lung but also may be due to altered glucose metabolism and a direct effect of cytokines on pulmonary cells.[28]

Laboratory studies suggest that both metabolic and respiratory acidosis protect the lung against injury, whereas correction of acidosis compounds the injury.[29,30] Two ventilator trials[31,32] demonstrating a positive impact on mortality in acute respiratory distress syndrome (ARDS) by limiting tidal volume and airway pressures differed widely on how they regarded the resultant hypercapnic acidosis. Whereas Amato et al[31] allowed elevation of the Pa_{CO_2} (permissive hypercapnia) and resultant acidosis, the ARDSnet group[32] aggressively corrected the hypercapnic acidosis by increasing the respiratory rate and allowing administration of sodium bicarbonate. There is growing evidence that not only may hypercapnic acidosis be

beneficial in lung injury,[29,33] but also the ARDSnet intervention aimed at correcting the acidosis may be deleterious.[30,34] These findings have not only promoted a greater tolerance of acidosis in ARDS but also increased reluctance to buffer the acidosis exogenously towards 'normal' values.

ASTHMA

Lactic acidosis often occurs in patients with acute severe asthma, and is often attributed to fatiguing respiratory muscles,[35] inadequate oxygen delivery to the respiratory muscles to meet the elevated oxygen demand[36] and liver ischaemia. However, severe lactic acidosis also occurs in sedated, paralysed mechanically ventilated patients who have no endogenous respiratory muscle activity.[37] Stimulation of beta-adrenergic receptors by beta agonists, including salbutamol and epinephrine, leads to a variety of metabolic effects including an increase in glycogenolysis, gluconeogenesis and lipolysis[38] thus contributing to lactic acidosis. Decrease of intravenous salbutamol infusions to less than 10 µg/min is usually associated with resolution of the acidosis. In asthma, lactic acidosis does not have specific prognostic implications.

MESENTERIC ISCHAEMIA

The diagnosis of mesenteric ischaemia can be challenging to make in the critically ill due to lack of clinical and diagnostic signs, difficulty transferring unstable patients for diagnostic imaging and concern about the deleterious effects of inappropriately administering contrast agents. An ischaemic bowel can produce large amounts of lactate, and the presence of lactic acidosis in the setting of acute abdominal disease has been proposed as an indicator of mesenteric ischaemia. Animal models have shown that lactate increases within 1 hour of induced intestinal ischaemia. In addition, elevated lactate at the time of diagnosis of mesenteric ischaemia is a predictor of mortality.[39] However, although plasma lactate is a very sensitive marker (100%) for detecting acute mesenteric ischaemia, the low specificity of this marker (42%) is a particular problem in the critically ill, who frequently have many plausible alternative diagnoses.

D-lactate is the isomer of lactate produced by intestinal bacterial metabolism and is not produced by humans. Experimental work suggests that ischaemic bowel allows its translocation into the systemic circulation; as D-lactate is not eliminated by the liver, plasma levels may be more specific markers of mesenteric ischaemia. However, many issues need to be clarified, including the effect of antibiotic therapy on the intestinal bacteria, before D-lactate could be considered as a bedside diagnostic test.[40] It is necessary to have a high index of suspicion for mesenteric ischaemia[41] in a deteriorating patient with an elevated lactate in the absence of a convincing alternative diagnosis, as identification of mesenteric ischaemia is frequently made first at laparotomy in the critically ill.

CARDIAC SURGICAL PATIENTS

Hyperlactaemia during cardiopulmonary bypass is relatively frequent and is associated with an increased postoperative morbidity.[42] Recent work has suggested that this 'on pump' hyperlactaemia is secondary to inadequate peripheral oxygen delivery (D_{O_2}), which creates a condition similar to cardiogenic shock leading to both direct lactate formation by dysoxic tissues and to catecholamine release, insulin resistance and hyperglycemia-induced lactate production.

The use of epinephrine after cardiopulmonary bypass precipitates lactic acidosis in some patients.[43] This phenomenon is probably beta agonist mediated, is associated with increased whole body blood flow and resolves after substitution of norepinephrine. However, there is emerging evidence that the severity of lactic acidosis following cardiac surgery is related to certain genetic polymorphisms in tumour necrosis factor and interleukin-10 genes.[44] Similar to asthma, lactic acidosis associated with the administration of epinephrine in this setting does not have the adverse implications of lactic acidosis associated with shock.

OTHER UNDERLYING DISEASES

In patients with cancer, anaerobic glycolysis may be increased whereas hepatic lactate metabolism is impaired by tumour replacement. Diabetic patients may present with shock, but in non-insulin-dependent diabetes there may also be a defect in pyruvate oxidation, and in diabetic ketoacidosis ketones may also inhibit hepatic lactate uptake. Thiamine and biotin are essential co-factors for pyruvate dehydrogenase activity and for conversion of pyruvate to oxaloacetate. Malnutrition (beri-beri) and inadequate parenteral nutrition have therefore been associated with lactic acidosis due to deficiencies of these cofactors. In these cases, pyruvate accumulation increases lactate production.

METFORMIN-ASSOCIATED LACTIC ACIDOSIS (MALA)

Metformin is an oral biguanide used widely in type 2 diabetes mellitus, as it has been shown to decrease cardiovascular morbidity and mortality.[45,46] Metformin-associated lactic acidosis is a rare, but very serious, complication of its use. Two years after its introduction into the US market, an incidence of MALA of 2–9 cases per 100 000 patients treated with metformin each year together with a mortality of up to 50% was reported.[47] A recent study in an Australian tertiary intensive care unit found an incidence of MALA of 6 per 1000 ICU admissions, and a mortality of 29%.[48] A European study

found that MALA accounted for 0.84% of all ICU admissions and was associated with a mortality of 30%.[49] In most cases, MALA occurs when the contraindications of metformin have been overlooked or, more commonly, when acute renal failure develops and leads to metformin accumulation.[45,50] Risk factors for developing lactic acidosis while on biguanide treatment include age >60 years, decreased cardiac, hepatic or renal function, diabetic ketoacidosis, surgery, respiratory failure, ethanol intoxication and fasting.[51]

The pathophysiology of MALA remains unclear, and there continues to be controversy about the exact role of metformin in the development of lactic acidosis. A recent Cochrane analysis analysed pooled data from all prospective comparative trials and observational cohorts studies up to 2009 and concluded that there was no current evidence that metformin is associated with an increased risk of lactic acidosis compared with other antihyperglycaemic treatments.[50] However, MALA continues to be reported, frequently in ICU patients,[48,49,52,53] including the Australian cohort described above in which other causes of lactic acidosis were excluded before a diagnosis of MALA was made.[48]

Although the mechanism of MALA is not fully understood, it is thought that biguanides may inhibit oxidative metabolism, and increase the concentration of NADH, reduce gluconeogenesis and suppress gastrointestinal absorption of glucose.[51] A recent retrospective study comparing 10 MALA patients with 187 patients with lactic acidosis of other origin (LAOO) found that the prognosis of MALA was significantly better compared with similarly severe LAOO.[53] Survival of patients with an arterial pH<7.00 was significantly better (50% versus 0%) if MALA was the underlying condition compared with LAOO.[53]

OTHER DRUGS AND TOXINS

The list of potential drugs and toxins that may contribute to the development of lactic acidosis continues to grow. Nucleoside reverse transcriptase inhibitors (NRTIs) used in the treatment of HIV-positive patients cause injury to the mitochondria, which can lead to lactic acidosis. However, NRTI-induced lactic acidosis is rare and is often associated with hepatic steatosis.[54] Acute ethanol intoxication can precipitate lactic acidosis, as ethanol oxidation increases the conversion of pyruvate to lactate and inhibits other pathways of pyruvate accumulation. Underlying alcoholic liver disease and thiamine deficiency may exacerbate the lactic acidosis. Propylene glycol has also been associated with lactic acidosis as it is oxidised by alcohol dehydrogenase in the liver to lactate and pyruvate.[55] It is used as a diluent in many medications such as phenytoin, phenobarbital, lorazepam, diazepam, digoxin and nitroglycerin and, as such, is the most common alcohol intoxication in ICUs.[56]

D-LACTIC ACIDOSIS

D-lactic acidosis is a unique form of lactic acidosis that occurs in patients with short-bowel syndrome, a history of jejuno-ileal bypass surgery or chronic pancreatic insufficiency. Since it was originally described in 1979,[57] there have been numerous reports. Patients typically present with a high-anion-gap metabolic acidosis and neurological manifestations including slurred speech and confusion, triggered by ingestion of large amounts of carbohydrate.

D-lactate is an end-product of the anaerobic metabolism of organic acids produced in the gastrointestinal tract from bacterial metabolism of undigested fibre, sugar and starch.[58] In the setting of carbohydrate malabsorption, the higher concentration of organic acids leads to a decrease in intraluminal pH favouring overpopulation of bacteria such as *Lactobacillus*, one of the main D-lactate-producing bacteria. As D-lactate is metabolised slowly, it can accumulate following a large carbohydrate load. D-lactic acidosis is characterised by a normal lactate level as the assay for lactate measures only L-lactate; a D-lactate level must be specifically requested if D-lactic acidosis is suspected.

CLINICAL PRESENTATION

Patients present with clinical signs appropriate to their primary disorder. Their lactic acidosis is usually evident only after laboratory testing. In critically ill patients with shock, however, the severity of lactic acidosis can be a valuable monitor of the efficacy of resuscitation. Repeated measures of arterial blood gases and blood lactate concentrations are required. In hypovolaemic shock, resolving lactic acidosis along with the clinical signs of improving perfusion is one of several indicators of successful resuscitation. Conversely, failure of lactic acidosis to resolve in hypovolaemic shock suggests inadequate resuscitation or another undetected or unresolved clinical problem. In patients with severe lactic acidosis,[1] a blood lactate concentration of 5 mmol/L indicated a mortality approaching 80%; survival was best in patients whose hyperlactaemia resolved. In septic shock there are many contributors to lactic acidosis, so the time course of acidosis resolution in this setting is a less reliable indicator of the adequacy of shock resuscitation.

Lactic acidosis may also occur in critically ill patients in the absence of shock. Examples include hypermetabolic states where accelerated aerobic glycolysis may contribute (trauma, burns, sepsis), conditions with increased muscle activity (seizures) and during exogenous lactate administration (lactate-buffered haemofiltration fluid). In many of these patients (e.g. patients with seizures) very high blood lactate concentrations have no prognostic implications because the acidosis is rapidly cleared.

CARDIAC DYSFUNCTION – ASSOCIATION, CAUSE OR RESULT OF LACTIC ACIDOSIS

Cardiac dysfunction is common in shocked patients with lactic acidosis and it has often been considered that therapies for lactic acidosis would improve cardiac function. However, cardiac dysfunction in these patients is probably instead due to other factors, with cytokines (TNF-α, interleukins) being the major cause in septic shock, with lactic acidosis a consequence or association rather than a cause of cardiac dysfunction. In lactic acidosis, some clinicians recommend normalisation of arterial pH based on two assumptions: (1) that acidosis causes cardiac dysfunction, and (2) that patients are better with 'normal' laboratory values.[59] Both of these assumptions are incorrect in most critically ill patients. While early research in isolated muscle, isolated heart preparations, animal models and clinical case reports supported the view that acidosis decreased cardiac function and decreased the haemodynamic response to catecholamines, later large animal studies in which preload, afterload and heart rate were carefully controlled found only marginal effects of lactic acidosis on contractility.[2,60] Also, laboratory reports of deceased cardiac function during acidosis studied an arterial pH much lower (pH 6.6–6.9) than that usually observed in critically ill patients.[61] Increasing experience with permissive hypercapnia on ARDS and asthma has supported the view that patients with respiratory acidosis have fewer complications and better outcomes when normal values are not targeted. Perhaps surprisingly, the major haemodynamic effect of acute hypercapnic acidosis in ARDS and asthma was increased cardiac output and vasodilation, not cardiac depression.[62] Therefore, targeting normal values in lactic acidosis is also unlikely in itself to be beneficial, and may be harmful.

MANAGEMENT

GENERAL

The principles of management of patients with lactic acidosis are to diagnose and correct the underlying condition (where possible), and restore adequate tissue oxygen delivery. In critically ill patients, lactic acidosis is often an indicator of major patient pathology. Therefore the main focus is to identify and treat the cause rapidly. A clinical examination and search for occult sepsis, inadequate resuscitation, localised ischaemia or cardiovascular failure are urgently required. In each case, after diagnosis and initial management, lactic acidosis may then be used as an ongoing monitor of disease progression or resolution.

TREAT THE PRIMARY DISORDER

Specific therapies and supports must be directed at each underlying cause. In hypovolaemic and cardiogenic shock, restoration of an adequate global oxygen delivery is required. Vasoconstrictors may worsen tissue perfusion and should only follow adequate intravascular volume and appropriate cardiac support. In septic shock, antibiotics appropriate to cover all likely sources of infections are a priority and in patients with possible ischaemic gut, surgery may be required for both diagnosis and therapy. Postsurgical gastrointestinal leaks may sometimes be difficult to diagnose, may not be detectable on computed tomography and require early laparotomy. In status epilepticus, lactic acidosis is a result of muscle activity and rapid use of effective anticonvulsants is indicated. In diabetic ketoacidosis, insulin, appropriate fluid and treatment of precipitants enable resolution of all metabolic abnormalities, including associated lactic acidosis. In thiamine deficiency, highlighted during a nationwide American shortage of multivitamins for patients receiving total parenteral nutrition,[63] high-dose intravenous thiamine corrected both the vasodilated shock and associated lactic acidosis. In acute severe asthma, lactic acidosis is commonly a result of high-dose intravenous beta-agonist therapy.[43] Salbutamol dose reduction usually resolves the problem. In vasodilated patients after cardiopulmonary bypass, lactic acidosis may also be related to beta-agonist therapy and resolves after substitution of intravenous epinephrine with norepinephrine. In these cases, lactic acidosis is not related to decreased tissue perfusion and adverse effects upon prognosis have not been noted. Patients with human immunodeficiency virus (HIV) receiving nucleoside analogue reverse transcriptase inhibitor (NRTI) therapy have a high incidence of hyperlactaemia (8.3%), which can progress to a rapidly fatal metabolic lactic acidosis syndrome. These patients with NRTI-induced mitochondrial dysfunction require withdrawal of the therapy (if lactate >5 mmol/L) and close monitoring.[64]

HYPERVENTILATION

Hyperventilation is a normal compensatory response to metabolic acidosis in conscious patients. Therefore in mechanically ventilated patients with lactic acidosis, clinicians will usually use some hyperventilation to correct acidaemia partially. Clearly in patients with pulmonary pathology, hyperventilation may be difficult or inappropriate, and in some patients, hyperventilation increases intrathoracic pressure, decreases venous return, decreases cardiac output and exacerbates the cause of lactic acidosis.

BICARBONATE

The use of bicarbonate therapy for the treatment of lactic acidosis continues to be controversial.[2,59,65,66] It was thought that correction of the acidosis through the administration of bicarbonate might reverse depressed cardiac performance; however, there is no evidence in critically ill patients that lactic acidosis depresses cardiac function, and laboratory studies report minimal

depression in large animals.[60,67] Further, not all studies have actually demonstrated a rise in pH after the administration of bicarbonate.[68] One reason for these findings is that sodium bicarbonate also has adverse effects including acute hypercapnia and ionised hypocalcaemia,[61] which outweighs potential benefits in patients. Hypercapnia may increase intracellular acidosis (CO_2 crosses cell membranes rapidly) and hypocalcaemia decreases myocardial contractility.[69] Other side-effects of bicarbonate occur because bicarbonate is a hypertonic solution and include acute intravascular volume overload and cardiac depression. In addition, bicarbonate increases lactate production by increasing the activity of the rate-limiting enzyme phosphofructokinase, shifts the haemoglobin–oxygen dissociation curve, increases oxygen affinity of haemoglobin and thereby decreases oxygen delivery to tissues.

While some clinicians continue to use bicarbonate in patients with a pH<7.20, the most recent Surviving Sepsis guidelines published in 2008 strongly recommend against the use of bicarbonate when treating hypoperfusion-induced lactic acidaemia in patients with a pH≥7.15,[70] whereas others have recommended a lower target pH of 7.00 or less.[66] There are no large randomised controlled trials of the use of bicarbonate in lactic acidosis, and the only two randomised crossover studies in critically ill patients with lactic acidosis and shock found no improvement in cardiac function or any other beneficial effects of pH correction.[61,71] As such, bicarbonate has never been shown to be beneficial in any clinical trial of patients with lactic acidosis and its use in these patients is not recommended, regardless of the degree of acidaemia.[2]

However, there are two specific subgroups of patients with lactic acidosis in whom bicarbonate may be considered. Patients with pulmonary hypertension and right heart failure (e.g. lung transplant recipients) may have pulmonary vasoconstriction, which is exacerbated by acidosis. In these patients, although there are other useful therapies including inhaled nitric oxide and partial pH correction, it may improve right heart function. Secondly, patients with significant ischaemic heart disease and lactic acidosis may be at increased risk of major arrhythmias because severe acidosis lowers the myocardial threshold for arrhythmias. In both of these subgroups, slow bicarbonate infusions to keep the arterial pH above 7.15 may be justified.

ALTERNATIVE THERAPIES

CARBICARB®

Carbicarb® is an equimolar mixture of sodium carbonate and sodium bicarbonate that does not generate carbon dioxide and may therefore have fewer adverse effects than bicarbonate.[72] There is limited clinical research associated with Carbicarb®, and though it has been shown to increase intracellular pH and have fewer haemodynamic adverse effects than bicarbonate (in animal models), it does not address the underlying cause of lactic acidosis and is not in clinical usage.

DICHLOROACETATE

Dichloroacetate (DCA) stimulates the phosphate dehydrogenase complex, the rate-limiting enzyme that regulates entry of pyruvate into the tricarboxylic acid cycle, and thereby facilitates the oxidation of lactate. Although it has been shown to increase arterial pH and decrease lactate concentrations,[73] a large multicentre randomised clinical trial in patients with lactic acidosis found no benefits for either haemodynamics or patient outcome.[74] This study is the best evidence currently available to support the view that correction of lactic acidosis in critically ill patients without improving the underlying primary disorder has no overall impact on patient outcome. DCA is not available commercially.

TRIS/THAM

Tris-hydroxymethyl aminomethane (THAM) is a commercially available weak alkali rarely used as a clinical therapy because of concerns about side-effects that include hyperkalaemia, hypoglycaemia, extravasation-related necrosis and neonatal hepatic necrosis. In acute lung injury, THAM has been demonstrated to be an effective buffer in ventilated patients as it is not associated with an increased CO_2 load and is capable of ameliorating some of the haemodynamic effects of hypercapnia.[75,76] However, it is unclear whether buffering of hypercapnic acidosis in acute lung injury patients is of any benefit. A trial of a single dose of sodium bicarbonate compared with THAM in ICU patients with a mild metabolic acidosis found that both had similar alkalising effects, although the effect of sodium bicarbonate was longer lasting. As THAM did not increase Pa_{CO_2}, it was recommended in patients with mixed acidosis with high Pa_{CO_2} levels.[77] There is no evidence to show that administration of THAM in patients with lactic acidosis improves outcome.

DIALYSIS/HAEMOFILTRATION

Haemofiltration and continuous renal replacement therapies (CRRT) have been promoted as treatments for lactic acidosis, with several theoretical advantages. Bicarbonate-based haemodialysis can assist in treatment of acidosis through diffusion of bicarbonate from the dialysate into the serum without the risk of volume overload, hypernatraemia or hyperosmolality. Studies have shown improvements in acid–base balance with bicarbonate-based CRRT,[78,79] although controlled clinical trials showing an improvement in outcome are lacking. A study of 10 critically ill patients with acute renal failure and stable lactate concentrations found that, following an infusion of sodium lactate, bicarbonate-buffered haemofiltration was ineffective, contributing to less than 3% of lactate clearance.[80] They concluded that continuous veno-venous haemofiltration with dialysis cannot meet lactate overproduction.[80]

However, in lactate-intolerant patients (i.e. those with shock-induced lactic acidosis and/or liver disease), the use of lactate-based dialysis fluid may overload the patient's metabolic capacity for lactate, particularly if high-volume haemofiltration is employed.[81] In these patients, bicarbonate-based replacement fluid should be chosen. In addition, there are some case reports that high-volume renal replacement therapy may be beneficial in severe MALA,[82,83] as it efficiently removes metformin by diffusion through the dialysis membrane; however, no controlled studies have been published.

Acute cardiac syndromes, investigations and interventions

Bradley Power

Cardiovascular disease (CVD) accounts for 1 in 3 deaths in Western industrialised society, with coronary artery disease (CAD) being responsible for about half of these.[1] In persons over age 40, acute myocardial infarction (MI) is the cause of approximately 20% of all deaths. Up to 70–80% of these deaths occur outside hospital. Of those who die acutely, 50–65% have no previous history of cardiac disease. Of patients admitted to hospital, early mortality is 5–7%[2–4] (much higher in at-risk groups) and may rise to 9–11% by 12 months.[2] Lowering in-hospital and longer-term mortality from CAD requires us to identify rapidly patients who are at risk and to implement evidence-based treatment regimens.

MYOCARDIAL INFARCTION

MI is present when there is evidence of myocardial necrosis in a clinical setting consistent with myocardial ischaemia. Diagnosis is usually made on the basis of clinical suspicion, although tests such as electrocardiography (ECG) and biomarkers, echocardiography or autopsy findings are required to confirm the diagnosis.

Acute MI can occur in association with or result from a number of different pathological and epidemiological mechanisms (**Box 20.1**).[5] Each mechanism may have a different long-term prognosis despite similar biomarker and ECG changes. The pattern of MI may be different in an emergency department (ED) population to that in a general intensive care unit (ICU) population. Such classifications may be clinically important when applying the results of clinical trials to clinical practice in different patient groups. Although there can be significant overlap, small amounts of myocardial necrosis can occur with heart failure, arrhythmias, pulmonary embolism or post cardiac procedures; these are perhaps best labelled 'myocardial injury'.[5]

ACUTE CORONARY SYNDROMES (ACS) (BOX 20.2)

ACS represent the largest group of patients developing MI. They describe the spectrum of patients who present with chest discomfort or other symptoms caused by acute myocardial ischaemia. ACS can be further divided into acute MI and unstable angina (USA). Both are invariably caused by recent thrombus formation on pre-existing coronary artery plaque leading to impaired myocardial oxygen supply. In this sense they differ from stable angina, which is usually precipitated by increased myocardial oxygen demand with severe background coronary artery narrowing. Both represent medical emergencies and are one of the most frequent causes of hospital and coronary care unit (CCU) admission.

An immediate clinical imperative is to identify those patients with ST-segment elevation (STE) as rapid reperfusion therapy is strongly indicated in this group.

AETIOLOGY AND RISK FACTORS

Atheroma deposits in the walls of coronary arteries provide the substrate for the development of ACS. Modification of risk factors is one of the most important means of decreasing the prevalence and mortality from CVD and MI. About 85% of patients presenting with their first myocardial infarction have at least one risk factor.

Cessation of smoking, lowering plasma cholesterol (diet and medications) and adoption of a more active lifestyle can all help prevent the development of CAD. Treatment of high-risk hypertensive patients produces a large and early reduction in stroke incidence (30–40%) and mortality, and a significant fall in MI (20–25%) and also heart failure (>50%).[6,7]

PATHOPHYSIOLOGY

Formation of thrombus upon disrupted, fissured or eroded atheromatous plaque is the usual precipitant of an ACS.[5,8–10] Atherosclerotic plaque formation is probably initiated by injury to the vessel wall that may commence even as early as childhood. Highly activated macrophages are attracted to the site of injury and differentiate into tissue macrophages. Macrophages incorporate bloodstream lipids into the connective tissue fibres of the plaque, forming a thrombogenic soft lipid core. Plaque development is slow, but is rapidly accelerated in people with risk factors.

'Vulnerable plaque' is often rich in lipid and covered by a thin fibrin cap. The cause of plaque rupture or fissuring is unknown but exposes thrombogenic lipid and collagen, which are potent activators of platelets.

Box 20.1 Universal classification of myocardial infarction

Type 1: Spontaneous myocardial infarction
Spontaneous myocardial infarction related to ischaemia due to a primary coronary event such as plaque erosion *and/or* rupture, fissuring, or dissection. The patient may have severe CAD but on occasion non-obstructive or no CAD.
Type 2: Myocardial infarction secondary to an ischaemic imbalance
In instances of myocardial injury with necrosis where a condition other than CAD contributes to an imbalance between myocardial oxygen supply and/or demand, e.g. coronary endothelial dysfunction, coronary artery spasm, coronary embolism, tachy-/brady-arrhythmias, anaemia, respiratory failure, hypotension, and hypertension with or without LVH.
Type 3: Myocardial infarction resulting in death when biomarker values are unavailable
Cardiac death with symptoms suggestive of myocardial ischaemia, and presumed new ischaemlc changes or new LBBB, but death occurring before blood samples could be obtained, before cardiac biomarkers could rise or on rare cases biomarkers were not collected.
Type 4a: Myocardial infarction related to percutaneous coronary intervention (PCI)
Significant cardiac biomarker rise from normal or by more than 20% if previously elevated. In addition, either:
i. symptoms of myocardial ischaemia, *or*
ii. new ischaemic ECG changes or LBBB, *or*
iii. angiographic loss of patency or persistent flow abnormalities, or embolization, *or*
iv. imaging demonstration of loss of viable myocardium or regional wall motion abnormality.
Type 4b: Myocardial infarction related to stent thrombosis
Myocardial infarction associated with stent thrombosis detected by coronary angiography or autopsy in setting of myocardial ischaemia and with a significant rise and/or fall of biomarkers.
Type 5: Myocardial infarction related to coronary artery bypass grafting (CABG)
Myocardial infarction associated with CABG arbitrarily defined by elevation of cardiac biomarker values from normal baseline to above 10 times the URL. In addition, either:
i. new pathological Q waves or LBBB, *or*
ii. angiographic documented new graft or new native coronary artery occlusion, *or*
iii. imaging evidence of new loss of viable myocardium or new regional wall motion abnormality.

Adapted from Thygesen K, Alpert JS, Jaffe AS, et al. Third universal definition of myocardial infarction. Eur Heart J 2012;33(20):2551.[5] *doi:10.1093/eurheartj/ehs184.* Modified with permission of Oxford University Press (UK) © European Society of Cardiology.

Development of thrombus upon this eroded plaque results from: (1) platelet adherence and activation, and (2) coagulation pathway activation.

Although many pathways initiate platelet activation, the final common pathway of thrombus formation is via activation of the glycoprotein (GP) IIb/IIIa receptor,

Box 20.2 Classification of acute coronary syndromes

Acute coronary syndrome (ACS)
A spectrum of clinical conditions characterised by acute chest pain or myocardial ischaemia. Pain is of recent origin or is more frequent, severe or prolonged than known angina, is more difficult to control with medication or occurs at rest or with minimal exertion.
ACS includes myocardial infarction with ST-segment elevation (STEMI), myocardial infarction in the absence of ST-segment elevation (NSTEMI) and unstable angina. An initial clinical subdivision of ACS is made on the presence or absence of ECG ST-segment elevation.
STEMI
Patients presenting with ST-segment elevation ACS will invariably display initial or subsequent troponin elevation, although the extent of myocardial infarction and complications may be significantly moderated by intervention.
NSTEACS
Patients who present without ST-segment elevation, may later (after testing of biomarkers) be determined to have:
i. *NSTEMI:* cardiac biomarkers elevated indicating myocardial infarction
ii. *Unstable angina:* no evidence of cardiac biomarker elevation.

the platelet surface membrane receptor for fibrinogen. Activated GP IIb/IIIa receptors cross-link fibrinogen between activated platelets, promoting the formation of platelet thrombi. Platelets aggregate to form 'white thrombus'; however, this thrombus is seldom totally occluding. Activation of coagulation pathways by exposed lipid and fibrin, as well as by the now-activated platelets, leads ultimately to thrombin activation and the laying-down of fibrin clot. Red cells are enmeshed in this so-called 'red thrombus' complex, which surrounds the 'white thrombus'. Sudden artery occlusion by thrombus may thus complicate even only moderate-sized plaque; 70% of ACS patients may have a <50% stenotic lesion and in only 14% is the underlying stenosis >70% of the lumen diameter (**Fig. 20.1**).

These processes have immediate relevance to treatment:

- Antiplatelet agents prevent platelet adherence and heaping, which limits and even reverses the development of 'white thrombus'. These agents may target the adenosine diphosphate (ADP) receptor (e.g. clopidogrel, prasugrel) or may inhibit cyclo-oxygenase (e.g. aspirin). Although aspirin has been the major antiplatelet agent and blocks synthesis of thromboxane A_2, it fails to block platelet activation by thrombin, ADP and collagen.[11]
- Fibrinolytic agents lyse 'red thrombus' but are not active against 'white thrombus'.
- Antithrombin agents (e.g. heparins) may limit thrombin activation. Current thrombolytic agents lyse fibrin and red cell thrombus, but paradoxically may increase surface thrombin activation.

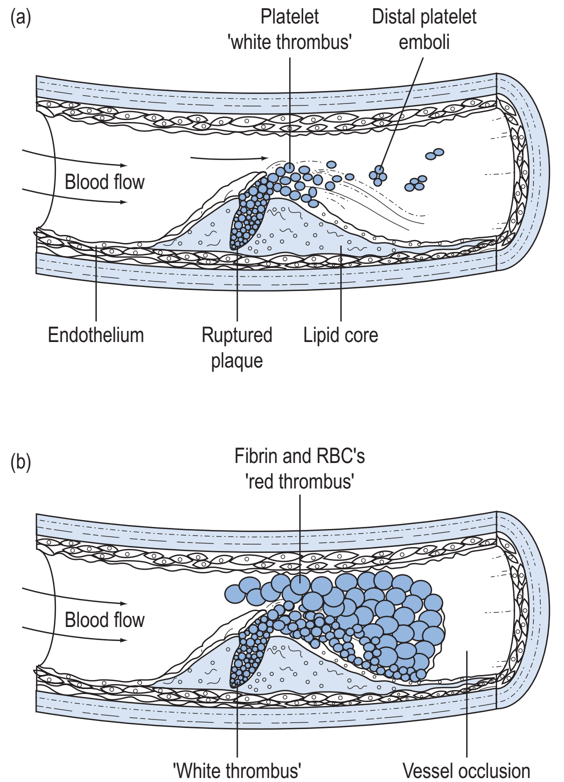

Figure 20.1 (a) Plaque rupture exposes thrombogenic lipid. 'White thrombus' is formed by adherent activated platelets. Coronary artery narrowing, distal platelet embolisation or arterial spasm can cause ischaemic myocardial pain and possible myocardial necrosis. This lesion is unstable and may lead to thrombin activation. 'White thrombus' is not removed by thrombolytic therapy. (b) Thrombin activation leads to a mesh of fibrin and red blood cells (RBCs) or 'red thrombus'. Arterial occlusion may result and, in arteries without adequate collateral circulation, myocardial necrosis follows. Complete arterial occlusion is suggested by ST-segment elevation on the electrocardiogram. Prompt reperfusion with thrombolytic therapy or with invasive coronary procedures may prevent extensive myocardial necrosis.

Totally occluding thrombus causes myocardial necrosis unless there is good collateral flow or the thrombus is rapidly cleared.[10] Occlusion is often accompanied by ST-segment elevation (STE) on the ECG. If thrombus is largely 'white thrombus', with minimal or non-occlusive red thrombus, STE is far less likely. Non-occlusive thrombus may be asymptomatic, may cause USA or MI, especially if spasm or distal embolisation of thrombus occurs. Although non-occlusive thrombus is less likely to be associated with early or sudden death, it is indicative of unstable plaque and is strongly associated with re-infarction and death in following months.

Ischaemic necrosis results in cellular disruption, loss of function, thinning and softening of the affected myocardium with an increase in ventricular compliance. As fibrosis takes place compliance is decreased. With time, there is often expansion of the infarcted segment and compensatory hypertrophy of unaffected myocardial cells (i.e. ventricular remodelling[10]). This can commence early after infarction, affecting overall ventricular function and prognosis.

Infarct size determines:

- left ventricular (LV) systolic function impairment
- stroke volume decrease
- ventricular filling pressure rise (leads to pulmonary congestion and hypotension that may impair coronary perfusion pressures and exacerbate the myocardial ischaemia)
- LV diastolic dysfunction.

CLINICAL PRESENTATION[4,5,12]

The diagnosis of myocardial ischaemia is usually made (suspected) on the basis of clinical history and ECG.[4,5]

HISTORY

Patients with myocardial ischaemia can present with chest pain or pressure, syncope, palpitations, dyspnoea or sudden death. Prodromal symptoms of unstable angina (USA) occur in the days preceding infarction in 20–60% of patients.

Typically, the pain of acute MI:

- is severe, constant and retrosternal, spreading across the chest
- lasts for more than 20 minutes and is without a clear precipitant
- may radiate to the throat and jaw, down the ulnar aspect of both arms and to the interscapular area.

Sweating, nausea, pallor, dyspnoea and anxiety are common.

The pain of USA may be similar but milder in nature. Features that may suggest it to be ischaemic are:[4]

- waxing and waning characteristics
- reproducibility upon minimal exertion or with emotion
- association with autonomic symptoms.

The pain may sometimes be atypical:

- epigastric (leading to possible misdiagnosis)
- confined to the jaw, arms, wrists or interscapular region
- burning or a 'pressure-like' sensation
- sharp or stabbing in nature
- reproduced by chest pressure.

These features do not necessarily exclude infarction.[5] Differential diagnosis includes:

- aortic dissection
- pericarditis.

Atypical or silent presentations are common: 25% of STEMI (ST-segment elevation myocardial infarction) patients and 45% of NSTEMI (non-ST-segment elevation myocardial infarction) patients may present without classic chest discomfort and are less likely to receive definitive treatment.[12] This presentation is more common in patients who are elderly, diabetic, have hypertension, who smoke or who take non-steroidal anti-inflammatory agents.

The assessment of clinical symptoms alone is insufficient for risk stratification and severity of pain does not usually correlate with the extent of infarction.

PHYSICAL EXAMINATION

Examination of patients with USA is often unremarkable. With more severe infarction and extensive myocardial injury, signs of autonomic activation (pallor, sweating, agitation, clamminess) as well as heart failure and even shock may be apparent. Pericardial friction rubs occur frequently after MI but are usually transient.

LV failure is associated with a higher mortality. Signs include gallop rhythm, tachycardia, tachypnoea and basal crackles. A fourth heart sound is often heard, but a third heart sound usually indicates a large infarction with extensive muscle damage. A systolic murmur may be present and may be transient or persistent. These murmurs can have prognostic significance and usually result from mitral regurgitation, due to either papillary muscle dysfunction or LV dilatation.

Cardiogenic shock, hypotension, oliguria and other features of low cardiac output are associated with particularly poor outcome. Shock may be present without hypotension and may develop many hours after onset of symptoms.[13] Right ventricle (RV) infarction results in hypotension and marked elevation of the jugular venous pressure (also seen with major LV dysfunction, usually in association with marked pulmonary venous congestion).

Conditions with similar presentations that do not benefit from thrombolysis are:

- pericarditis (auscultate for pericardial rub)
- aortic dissection (arterial pulses are compared; review chest X-ray if concerned).

INVESTIGATIONS

The presence of MI should also be qualified by:[5]

- anatomical location and size
- causation (e.g. MI Type 1–5) (see Box 20.1)
- time from occurrence (acute, early, late).

Technological advances allow accurate detection of very small infarcts (myocardial necrosis <1.0 g).

ELECTROCARDIOGRAPHY[14,15]

All patients presenting with symptoms suggestive of MI should have an ECG performed and interpreted within 10 minutes of arrival. The ECG is considered the initial single most important test for diagnosing and guiding the emergency treatment of MI. Patients experiencing myocardial ischaemia may have initial ECGs that reveal significant ST-segment elevation (STEACS) or that lack significant ST-segment elevation (NSTEACS). Serial ECGs may give information about the site, size and possible therapies.

Acute and complete occlusion of a coronary artery usually leads to serial ECG changes in leads subtending the area of ischaemia, where the:

- number of leads involved broadly reflects the extent of myocardium involved
- height of initial STE is modestly correlated with the degree of ischaemia
- acute resolution of STE correlates well with reperfusion.

Identification of classical acute and early changes where STEMI is present identifies patients in whom reperfusion therapy may interrupt, prevent or minimise myocardial necrosis (**Fig. 20.2**). These changes are not stereotyped and may vary significantly but include:

- *hyperacute* (0–20 minutes): tall, peaking T-waves and progressive upward coving and elevation of ST-segments
- *acute* (minutes to hours): persisting STE, gradual loss of R-wave in the infarcted area. ST-segments begin to fall and there is progressive inversion of T-waves
- *early* (hours to days): loss of R-wave and development of pathological Q-waves in area of ischaemia.

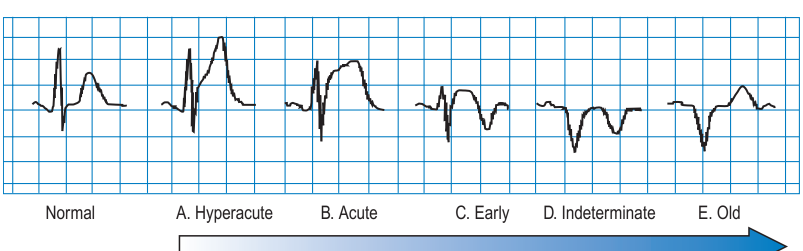

Figure 20.2 Total acute coronary occlusion leads to serial electrocardiogram changes. The evolution is variable and may be interrupted or altered by successful reperfusion. ST-segment elevation is an early and relatively specific indicator of the need for acute reperfusion in patients with acute coronary syndrome.

Return of ST-segments to baseline. Persistence of T-wave inversion

- *indeterminate* (days to weeks): pathological Q-waves with persisting T-wave inversion. ST-segments normalise (unless there is aneurysm)
- *old* (weeks to months): persisting deep Q-waves with normalised ST-segments and T-waves.

Clinical skill is needed to identify those ECG changes that are probably due to MI (true positive but also false negative). Other causes of STE and T-wave changes that should *not* receive thrombolytic therapy are shown in **Box 20.3**.[5,16]

Takotsubo syndrome is characterised by precordial ST-segment elevation, apical ballooning on echocardiography but normal vessels on angiography. It may follow the onset of recent severe stress and may cause up to 1–2% of STEMI. It has been recognised in critical illness.

Patients with ACS but without significant ST-segment elevation (generically, non-ST-segment elevation ACS (non-STEACS or NSTEACS), until further subdivided by biomarker studies) may still be at high risk of infarction and death. They probably have active, non-occluding thrombus or, if it is occluding, then some collateral flow is present. ECGs in these patients may be normal or display:[14,15]

- ST-segment depression
- STE (insufficient to meet thrombolysis criteria)
- T-wave inversion or 'normalisation' of previous inverted T-waves.

LOCALISATION OF INFARCTION[14,15]

The left anterior descending (LAD) coronary artery supplies the anterior two-thirds of the interventricular septum (septal perforators), the anterior and lateral wall of the LV (diagonal branches) and sometimes part of the RV. The left circumflex artery supplies the LV lateral (anterolateral marginal branches) and posterior walls, and occasionally its inferior aspect (posterior LV arteries: 15% of patients) and the posterior septum. The right coronary artery (RCA) supplies the RV wall, and usually the posterior septum and inferior (diaphragmatic) wall of the left ventricle (posterior LV arteries; 85% of people). The RCA is 'dominant' (as opposed to the circumflex) if it gives rise to the posterior descending coronary artery (PDA) (**Fig. 20.3**).

It is usual to use the ECG in initial clinical assessments to 'localise' the area of myocardial ischaemia. The pattern of lead involvement may assist with localisation of the MI (**Table 20.1**).[14,15] There is a reasonable correlation between the site of infarction as defined by the ECG, the occluded or 'culprit' coronary artery, and the infarcted region of myocardium. However, ECG localisation may differ from angiographic, echocardiographic and autopsy findings, especially where there is collateral circulation or previous coronary artery bypass grafting (CABG). Anterior wall infarctions usually result from occlusion of the LAD; inferior, true posterior (although the infarcted region may in truth be lateral)[15] and RV infarctions result from occlusion of the RCA or circumflex arteries.[14,15]

Common ECG patterns of infarction are shown in **Figure 20.4a, b**. Approximately 40–50% of patients present with anterior infarction and 50% with inferior infarction. Anterior wall infarctions may be extensive or localised (septal, anterior, lateral). Inferior infarctions may involve extension to the lateral, posterior or RV myocardium. Standard ECGs generally only record from anterior body leads and thus important ECG patterns that must not be missed are as follows.[14,17]

- True or 'strictly' posterior infarction involves 'mirror' changes in leads V_1 and V_2 and is important to diagnose because the amount of threatened myocardium is similar to that of inferior infarction. Usually there might be ST-elevation in inferior leads II, III, AVF that might not have met diagnostic criteria for reperfusion. These patients should receive reperfusion therapy, especially when non-standard posterior chest leads (V_7–V_9) show ST-elevation, even in the absence of ST-elevation in any of the standard 12-lead ECG leads. Such infarctions are usually actually lateral rather than posterior but the term 'posterior' is still retained.[14,17]
- RV infarction is usually concurrent with inferior wall infarction and very rare in isolation. A V_4R lead (V_4 lead in an equivalent position on the right anterior chest wall) is sensitive and specific for RV infarction and should be considered in patients with inferior MI.
- Resting ECG changes revealing significant ST-segment depression in eight or more body surface

Box 20.3 Electrocardiogram patterns mimicking ST-segment elevation myocardial infarction

Normal variant (non-ischaemic STE mainly V2–V3)
Early repolarisation (notched J-point mainly in anterolateral leads)
Metabolic disturbance (mainly hyperkalaemia, hypercalcaemia)
Drug toxicity
Brugada syndrome
Pre-excitation (Wolff–Parkinson–White syndrome)
Pericarditis
Myocarditis
Previous (old) myocardial infarction
LV aneurysm
Spontaneously reperfused myocardium
Apical ballooning syndrome (Takotsubo or 'broken heart') multiple causes, e.g. severe emotion, physical stress

Data from Thygesen K, Alpert JS, Jaffe AS, et al. Third universal definition of myocardial infarction. Eur Heart J 2012;33(20):2551,[5] and Pollak, P. and Brady W. Electrocardiographic patterns mimicking ST segment elevation myocardial infarction. Cardiol Clin 2012;30(4):601–15.[16]

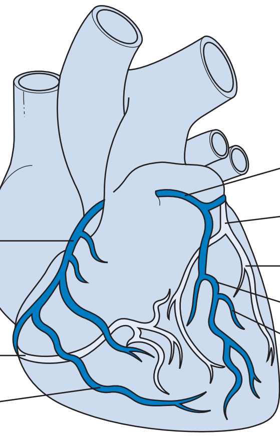

Figure 20.3 Coronary artery anatomy. The left anterior descending artery (LAD) supplies the anterior two-thirds of the interventricular septum (septal perforators), anterior and lateral wall of the left ventricle (LV: diagonal branches) and sometimes part of the right ventricle (RV). Circumflex (Cx) supplies the LV lateral (anterolateral marginal branches) and posterior walls, and occasionally its inferior aspect (posterior LV arteries: 15% of patients) and the posterior septum. The right coronary artery (RCA) supplies the RV wall, and usually the posterior septum and inferior (diaphragmatic) wall of the LV (posterior LV arteries; 85% of people). The RCA is 'dominant' (as opposed to the circumflex) if it gives rise to the posterior descending coronary artery (PDA) and the posterior left ventricular arteries.

Table 20.1 Electrocardiogram patterns of myocardial injury

ANTERIOR WALL	ST-SEGMENT ELEVATION	
'Extensive anterior' (antero-lateral)	V_1–V_6, I, aVL	Proximal LAD occlusion
Septal	V_1–V_3, disappearance of septum Q in leads V_5,V_6	LAD-septal branches
Anterior (localised or true)	V_2–V_5, I, aVL	Diagonal (supplies anterior LV wall) Occasionally marginal branch of CX
Lateral	V_5,V_6, I, aVL,	Distal LAD or circumflex
INFERIOR WALL		
Inferior (localised)	II, III, aVF	RCA (80%) or post-lateral branch of CX (20%)
Inferior (extended)	II, III, aVF ***plus***	
Infero-lateral	I, aVL, V_5, V_6	RCA or dominant CX
Infero-posterior	V_7, V_8, V_9 with ST depression V_1–V_2	RCA post descending branch or postero-lateral branch of CX
Right ventricular	V_1, V_3R, V_4R	Proximal RCA
*Posterior (localised)	V_7, V_8, V_9. (Elevation II, III, aVF may not be marked) Initial V_1,V_2 ST depression may evolve to tall R waves	RCA

The sensitivity, specificity and predictive value of these patterns in determining the culprit artery (as subsequently determined by angiography) are not perfect. This is especially true of occlusions of the RCA and CX.
*Posterior infarctions are usually identified as lateral on angiography but guidelines suggest that the name be retained. Lack of ST elevation on standard leads may lead to failure to appreciate that they are a STEMI and will benefit from reperfusion therapy. Clinicians should also be aware of novel patterns of ischaemia and 'STEMI equivalents' that may include 'Wellens phenomenon', STE elevation in aVR, ST changes in presence of LBBB and the de Winter ST/T complex.
RCA=right coronary artery; LAD,=left anterior descending coronary artery; CX=circumflex coronary artery.

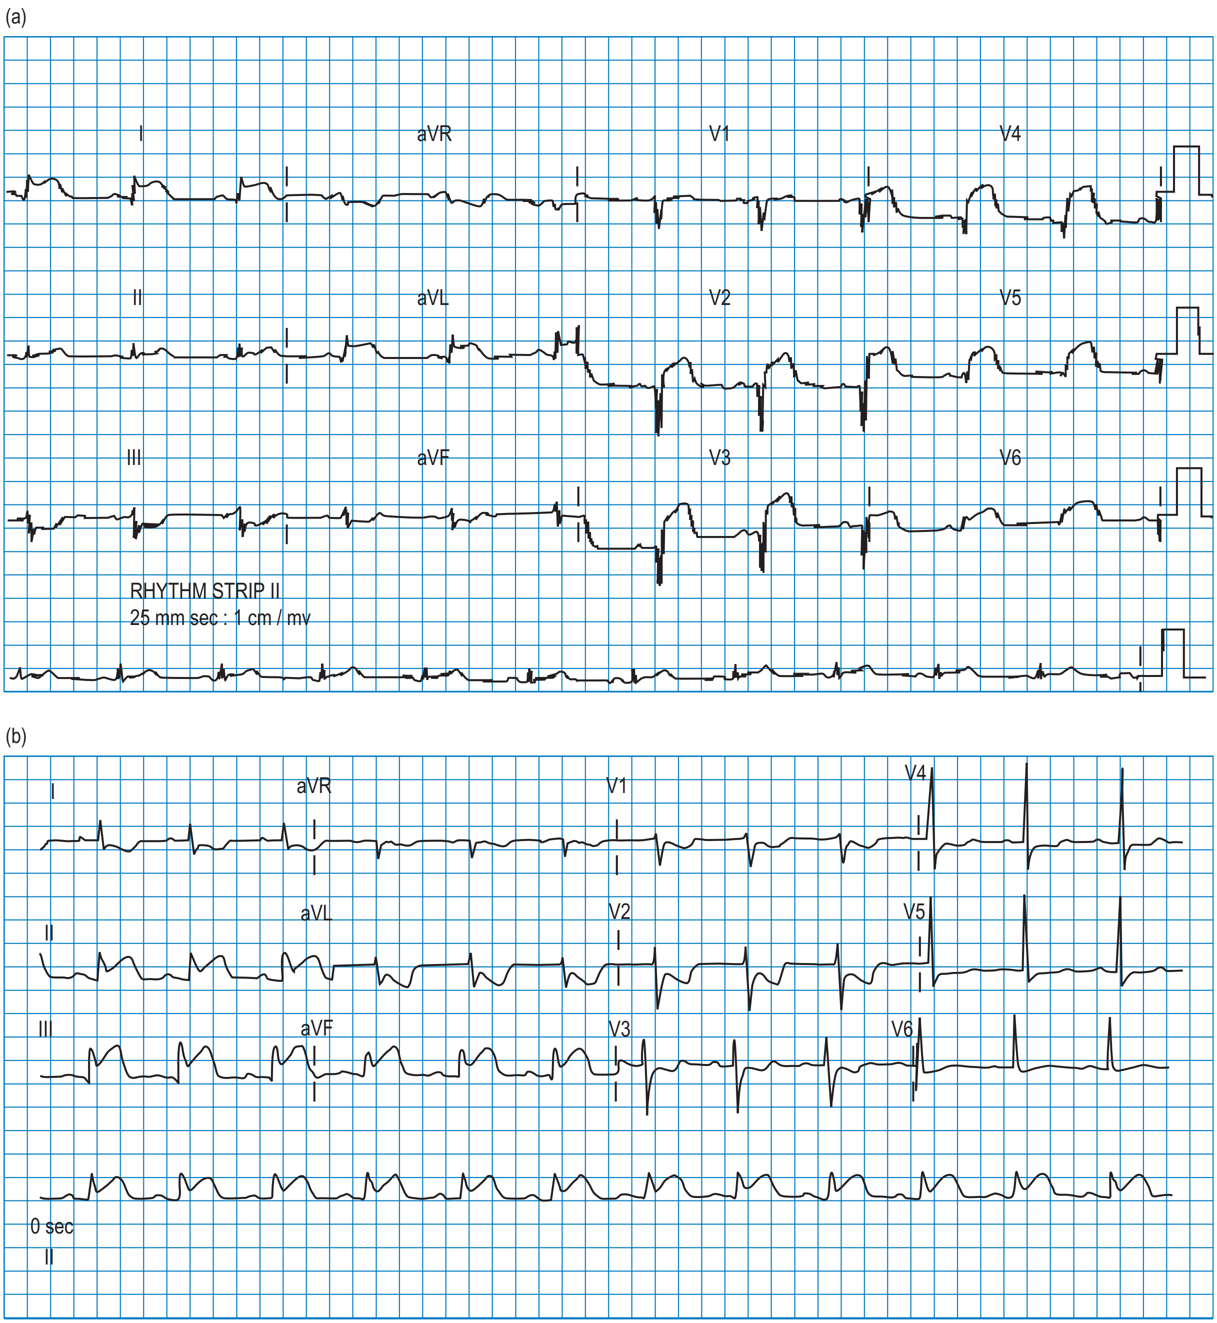

Figure 20.4 (a) Evolving antero-lateral MI. There is ST-segment elevation (STE) in anterior leads V_2–V_6 and lateral leads I, aVL. There is loss of anterior R wave height, and reciprocal ST-segment depression in leads III and aVF. If within time frames or if shocked, urgent reperfusion is indicated. (b) Acute inferior myocardial infarction (STE in the inferior leads II, III and aVF). There is ST depression in leads I, aVL, V_1 and V_2. The addition of right-sided (V_4R) and posterior leads would help identify the presence of RV and posterior infarction (STE). Reciprocal ST-segment depression in leads remote from the site of infarction is a highly sensitive indicator of myocardial infarction. It may be seen in 70% of inferior and 30% of anterior infarctions.

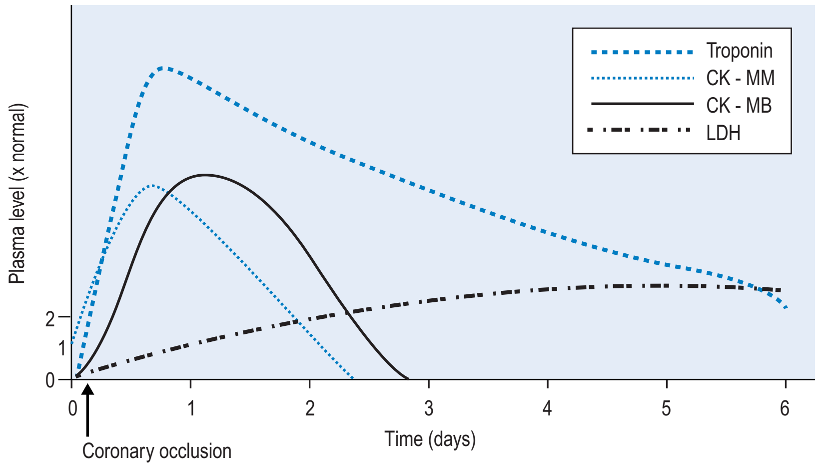

Figure 20.5 Serum biochemical marker changes after acute myocardial infarction. The sensitivity and specificity of cardiac troponins makes them useful for the early diagnosis of myocardial infarction. Their delayed fall may allow diagnosis where presentation is late. CK or CK-MB is useful if re-infarction with secondary biomarker rise is queried. LDH=lactate dehydrogenase.

leads coupled with STE in aVR and/or V_1 are highly suggestive of multivessel or left main coronary artery obstruction.[15]

- The specific pattern of deep T-wave inversion in V_2–V_4 with QT interval prolongation may suggest severe proximal LAD disease. It may occur after chest pain but be associated with imminent occlusion.[15]
- A normal ECG may be present in 15–20% of NSTEMI and does not exclude MI, although a normal ECG during pain is unusual.[14] Despite the absence of STE, a small percentage of patients progressively lose R-wave height and develop evidence of Q-waves and a small number progress to cardiogenic shock. The resting ECG does not have sufficient predictive value to stratify patients with NSTEACS reliably into those with infarction (NSTEMI) and those without (USA). Cardiac biomarkers are necessary to confirm myocardial cellular injury and meet diagnostic criteria for MI.

CARDIAC BIOCHEMICAL MARKERS (TROPONINS)[5] *(**FIG. 20.5**)*

The cardiac troponin (cTN) complex has three isoforms, two (cTnT and cTnI) of which are exclusively expressed (highly specific) in cardiac myocytes. Myocardial necrosis produces an initial release of troponin within the cell cytosol. Diffusion of this cytosolic troponin allows detection approximately 4–6 hours post infarct, with a peak usually at 12–24 hours. In acute injury there is a gradual return to normal within 7–14 days. This long tail on levels is thought to be due to secondary degradation of myofibrils with extended ongoing release. Renal failure prolongs excretion.

- High sensitivity and specificity of cardiac troponins has made them the gold standard for the confirmation of myocardial necrosis. Elevated levels should be taken as evidence of myocardial injury and, in the correct setting, as confirmation of MI.[5]
- Troponins should be checked in all patients with ACS. An acute rise and fall is usually desired to separate it from other causes of troponin elevation.
- cTn levels are more sensitive than creatinine kinase (CK). A third of people previously considered to have USA are now redefined as MI.[14,18]
- Troponins do not differentiate the cause of the myocardial injury (e.g. ischaemia, myocarditis, trauma), thus clinical context must always be considered.[5]

Troponin levels thus allow early and sensitive detection of myocardial necrosis. Troponins have significant clinical utility in guiding diagnosis and therapeutic planning.

- There is a strong correlation between troponin level, intracoronary thrombus and amount of threatened or ischaemic myocardium.
- Troponins identify groups who will derive benefit from therapies such as low-molecular-weight heparins (LMWHs), glycoprotein inhibitors (GPIs) and early percutaneous coronary intervention (PCI).

Troponins in critical illness[19,20]

The elevated levels of troponin in Type 1 MI (see Box 20.1) correlate well with risk stratification and predicted response to therapy. Cardiac-specific troponins are frequently elevated in critical illness (up to 40–50% of patients), including but not confined to sepsis, pulmonary embolus and renal insufficiency.[20] They fit the pattern of Type 2 MI, are of cardiac origin and are indicative of myocardial injury, but not necessarily of ‘unstable plaque’. Their elevation does correspond with adverse outcomes.

A study of >15 000 adult major non-cardiac surgical patients revealed that 11.6% developed postoperative troponin elevations that had a strong association with 30-day mortality,[19] both in-hospital and post-discharge (45% a vascular and 55% a non-vascular cause of death). Whether the underlying aetiology is unstable plaque

(Type 1 MI) or supply demand ischaemia (Type 2 MI) is unknown. These patients are often excluded from ACS trials and the post-surgery risk–benefit of therapies such as aspirin, clopidogrel, LMWHs and PCI is not known. Clinical context is necessary to decide those likely to have significant underlying CAD that may require acute or subsequent intervention.

ECHOCARDIOGRAPHY[21] *(SEE CH. 27)*

Two-dimensional transthoracic echocardiography with colour Doppler has good clinical utility as a non-invasive investigation during admission for an ACS. Its primary role is in assessing the degree of regional and global LV dysfunction.

Echocardiography detects regional wall motion abnormalities (RWMAs), which can help confirm or exclude the diagnosis of MI in the small percentage of cases where diagnosis is uncertain (e.g. left bundle branch block (LBBB) or old infarction with atypical presentations). RWMA and loss of wall thickening with contraction are often present in these cases if due to ischaemia, whereas their absence suggests that ischaemia is not acute. It is useful for excluding differential diagnoses (e.g. aortic dissection or pericardial effusions), again in a small percentage of patients.[5]

Echocardiography is useful subsequently and in ICU populations to:

- assess infarct size, especially if thrombolysis has interfered with biomarker measurement
- diagnose RV infarction and infarct extension
- allow bedside assessment of LV and RV function
- diagnose specific complications (e.g. mitral regurgitation, pericardial effusion, mural thrombus and myocardial rupture, including ventricular septal defect).

Transoesophageal echocardiography has an increasing role in the therapy of cardiogenic shock and complicated myocardial infarction.

Dynamic or graded intravenous (i.v.) dobutamine stress echocardiography (2–10 days after MI) can assess myocardial viability and distinguish non-viable myocardium from stunned myocardium. Superiority to standard exercise testing has not been proven.

RADIONUCLIDE STUDIES[22]

Practical problems limit the use of radionucleotide angiography in the ED diagnosis of ACS. Nevertheless, rest technetium-99n-sestamibi myocardial perfusion single-photon emission computed tomography (SPECT) is validated, excluding ACS in patients presenting to EDs with chest pain. The negative predictive value for excluding MI may exceed 99% and for excluding future cardiac events may be greater than 97%. Dynamic or functional radionuclide studies (Thallium-201 or SPECT) are useful in post-infarction risk stratification and are able to detect ‘threatened myocardium’.

STRESS TESTING

Stress testing may be useful in risk stratification and diagnosis of stable angina. Following infarction, the following may be of use:

- submaximal stress testing (to a heart rate of 120 beats/min), pre discharge, upon patients with an uncomplicated course
- maximal symptom-limited stress test 3–6 weeks post infarction.

CORONARY ANGIOGRAPHY AND LEFT VENTRICULOGRAPHY

Coronary angiography will also allow detection of other coronary artery disease and an assessment of LV function. It is the gold standard for the diagnosis (and often treatment) of CAD; however, the timing and need for this are determined by clinical risk. In the appropriate clinical setting, coronary angiography will usually identify a ‘culprit artery’ subtending an area of regional wall motion abnormality and additionally may allow definitive treatment of this abnormality. These indications are discussed later.

RISK STRATIFICATION OF ACUTE CORONARY SYNDROME (**FIG. 20.6**)[4]

An immediate goal is to identify patients with STEMI, who will then benefit from reperfusion therapy. This is almost always done on the basis of the presenting ECG.

STEMI

STEMI (including new, presumed new LBBB) with persistent pain is the most acutely lethal form of ACS and is usually due to complete occlusion of a coronary artery (>90% of patients).[18] It is an indication for reperfusion therapy. Such therapy may be successful and significantly reduce the size of the potential infarction, although some rise in troponin is usually inevitable. Patients who develop STE after admission should also then be stratified to this group.

Meta-analysis of trials involving nearly 60 000 patients revealed LBBB or STE on admission to be a strong indicator of benefits from reperfusion. Patients on trial entry with anterior STE had an absolute benefit of 37 lives saved per 1000 patients, patients with inferior STE 8 lives saved, and those in other locations 27 lives saved per 1000 patients treated.[23]

Guidelines advise early reperfusion therapy for ACS patients presenting with LBBB (new or presumed new) and that misdiagnosis is associated with high morbidity. Correct diagnosis is difficult as current data suggest that this group may be heterogeneous with multiple co-morbid conditions. Thus, perhaps only one-third of patients who present with LBBB may ultimately be shown to have ACS (occluded culprit artery), one-third non-ACS cardiac disease and perhaps one-third have non-cardiac disease. Non-pharmacological reperfusion

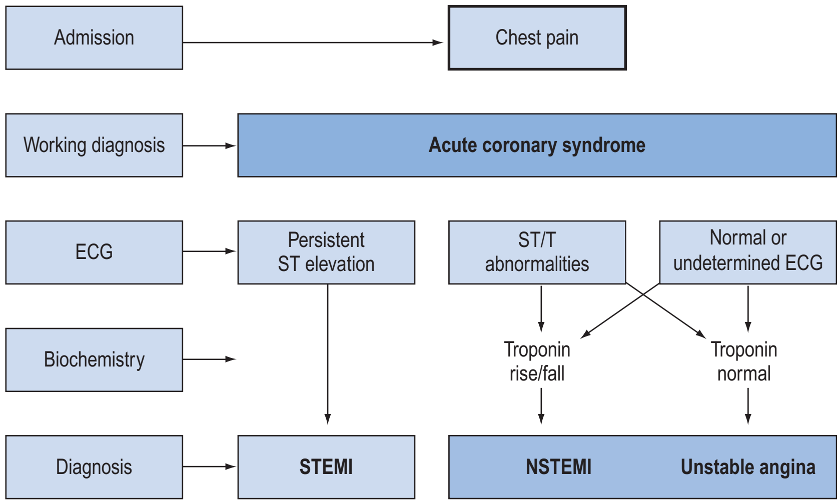

Figure 20.6 The spectrum of ACS. PCI=percutaneous coronary intervention; ECG=electrocardiogram; NSTEMI=non-ST-elevation myocardial infarction; STEMI=ST-elevation myocardial infarction. Physicians should obtain, interpret and stratify patients with ACS within10 minutes of arrival. STE in this clinical setting is usually due to complete coronary occlusion and most patients will ultimately have some biomarker elevation (STEMI). Rapid and sustained coronary artery reperfusion (PCI or fibrinolytic therapy) may significantly decrease myocardial damage. Well-organised systems of care should be in place to minimise delays. In patients without STE (non-STEACS), serial biomarker measurements may define those patients with elevated levels (NSTEMI) and those with ACS but normal biomarkers (unstable angina). Clinical review and further tests may lead to a non-ischaemic cause of chest pain in some patients. Subsequent echocardiography and imaging may help define the extent of injury, coronary anatomy pathology and its clinical importance. *(Adapted from Hamm et al, 2011[4] with permission. doi:10.1093/eurheartj/ehr236 'Adapted with permission of Oxford University Press (UK) © European Society of Cardiology'* http://www.escardio.org/guidelines.*)*

methods are thus perhaps favoured where the diagnosis is uncertain.[17,24]

Considerable variability in mortality risk exists among patients with STE. Readily available bedside clinical risk score tools may give insight into predicted 30-day mortality (**Fig. 20.7**).[25]

NSTEACS

Patients have ischaemic chest pain but have 'non-specific' ECG changes (normal, ST-segment depression or minimal elevation, T-wave inversion). After serial biomarker testing, these patients will later prove to have either USA if troponins remain normal or NSTEMI (elevated troponin). In contrast to fibrinolyis in STEMI, fibrinolysis in patients with ST-segment depression resulted in an excess of 14 deaths per 1000 patients treated and in patients with normal ECGs an excess of 7 deaths per 1000 patients.[23,26] Only 35–75% of patients have evidence of coronary thrombus formation and thrombolytic therapy is not beneficial in this group. Indeed, it is associated with worse outcomes.[18,23,27]

The therapy of NSTEMI aligns more clinically with that of USA than with that of STEMI. These two conditions, both forms of NSTEACS, represent a spectrum of disease and require common treatments directed at platelet inactivation and 'plaque stabilisation'. The term 'NSTEACS' recognises that they are clinically indistinguishable at presentation. Despite the heterogeneous nature of this group of patients and variable prognoses, early stratification using both ECG and troponins with simple clinical variables may define risk and guide evidence-based therapy (**Fig. 20.8**).[28] The more severe the ischaemia, the higher is the indication for more aggressive anticoagulation and invasive procedures.

Figure 20.9 displays the incidence of major coronary events over the following 6 months in patients presenting with and without STE. ST-segment depression has lesser early mortality but a similar or higher mortality at 6 months and at 10 years than those presenting with STE.[29]

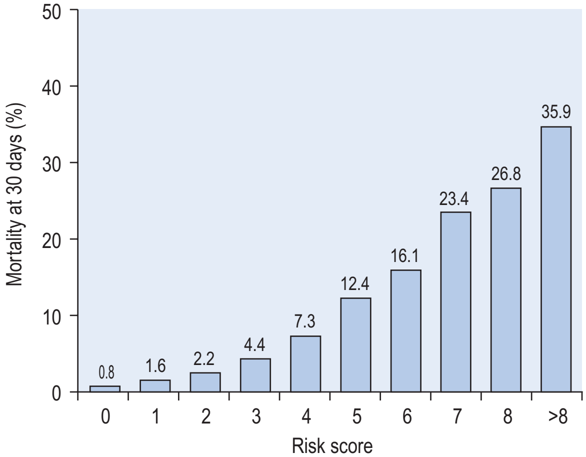
Q-wave MI (QwMI) or non-Q-wave MI (NqwMI) are older terms used to describe MI. The 10-year mortality of NqwMI (70%) is 10% higher than that of QwMI.

IMMEDIATE MANAGEMENT OF ACUTE CORONARY SYNDROMES

PREHOSPITAL CARE

Fifty per cent of deaths from MI occur within the first hour of symptom onset. These deaths are usually due to ventricular fibrillation (VF). Treatment is defibrillation.

Review of trials comparing prehospital to in-hospital thrombolysis in highly selected patients suggests improvement in 30-day mortality (17% decrease, 95% CI 2–29%).



At risk (%)	12	22	16	16	14	9	8	3	2	1

One point each of:	· Age 65–74 / ≥ 75 years	2/3 points
	· SBP <100	3 points
	· Heart rate > 100	2 points
	· Killip II–IV	2 points
	· Anterior STE or LBBB	1 point
	· Diabetes, h/o HTN or h/o angina	1 point
	· Weight < 67 kg	1 point
Possible score 0–14	· Time to Rx > 4 hours	1 point

Figure 20.7 STEMI-TIMI: TIMI (thrombolysis in myocardial infarction) risk score for STEMI is a simple bedside evaluation for predicting 30-day mortality. STE=ST elevation; h/o=history of. *(From Morrow et al, 2000,*[25] *with permission.).*

Number	85	339	627	573	267	66
(%)	4.3	17.3	32.0	29.3	13.6	3.4

Figure 20.8 NSTEMI-TIMI: the thrombolysis in myocardial infarction (TIMI) score is used to estimate the risk of the composite end-point of death, MI, or need for urgent cardiac catheterisation (vertical axis) at 14 days in patients with USA or NSTEMI. Each risk factor is worth 1 point for a maximum score of 7. CAD=coronary artery disease. *(Adapted from Antman et al, 2000.*[28]*)*

IMMEDIATE HOSPITAL CARE

1. Cardiac monitoring.
2. Oxygen[18,30] (2–4 L/min via facemask or nasal prongs) is recommended for breathless or hypoxic patients although benefits of routine use in uncomplicated ACS are uncertain.[26,31]
3. ECG (12-lead) should be taken within 5 minutes of arrival.
4. Aspirin at 160–325 mg should be chewed and swallowed on arrival. Clopidogrel or prasugrel is given if there is aspirin sensitivity or high risk.[18,30] Dual antiplatelet therapy is usually recommended.
5. Sublingual nitroglycerine (GTN) may have beneficial effects. Side-effects include hypotensive reactions and a hypotensive bradycardic response (the Bezold–Jarisch reflex).
6. Venous access is usually established.
7. Pain relief should be provided. Pain produces catecholamines, which increase ischaemia. GTN, reassurance and small incremental boluses (1–2 mg) of morphine can be given. Admission NSAIDs should be ceased immediately as use in the week prior to admission is associated with increased risk of death and cardiac complications.[18,32] Pain relief is best served by rapid reperfusion.[33]
8. Rapidly identify ACS patients with STE or new and presumed new LBBB (**Box 20.4**).[30,33] Emergent reperfusion therapy is of critical importance ('Time is muscle'). Hospital protocols with evidence-based goals should exist and outline the strategies to achieve them.
9. Emergent angioplasty (or rapid transfer to a centre capable of this) is generally superior to thrombolytic therapy (see following). Thrombolysis should generally be performed where the benefits of urgent PCI cannot be obtained.
10. Pulmonary oedema is treated with upright posture, i.v. furosemide, GTN or i.v. nitrates and, if severe, with continuous positive airway pressure ventilation.
11. Beta-adrenergic blockers (oral) should be commenced in haemodynamically stable patients as soon as possible (usually after thrombolytic therapy has been given or before PCI) but only where contraindications do not exist.
12. Prophylactic antiarrhythmics are *not* administered.

ACUTE MANAGEMENT OF STEMI (FIG. 20.10)[30]

REPERFUSION THERAPY

Prompt reperfusion therapy (mechanical or pharmacological) to establish coronary artery flow is the 'gold standard' for STEMI therapy and is far superior to non-reperfusion management.

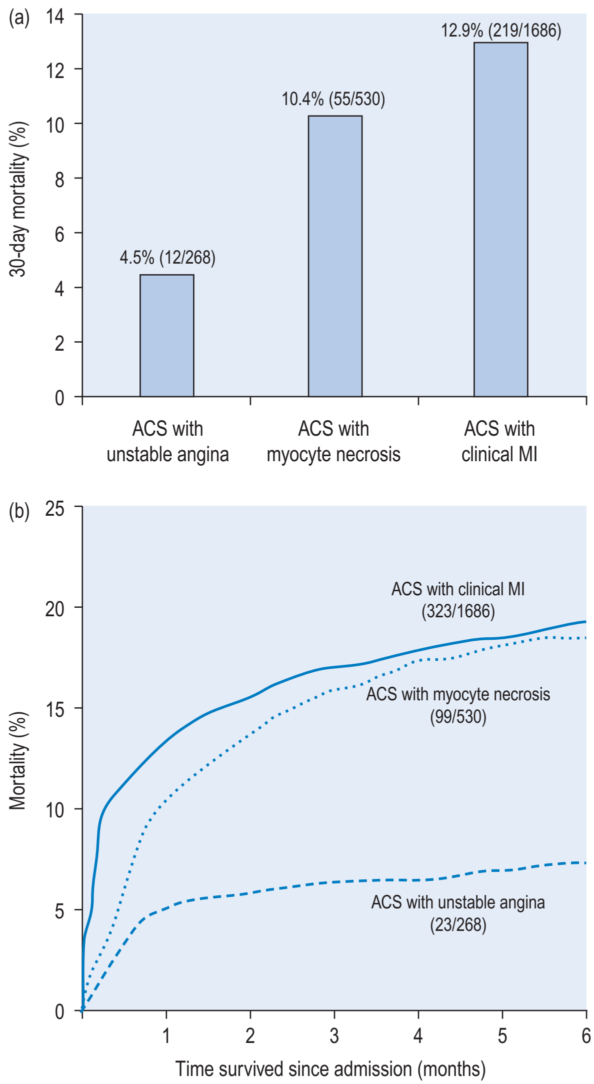

Figure 20.9 (a) Thirty-day mortality according to British Cardiac Society category. (b) Kaplan–Meier survival area curves for events from admission to 6 months. ACS=acute coronary syndrome. *(Reproduced from Das R, Kilcullen N, Morrell C et al. The British Cardiac Society Working Group definition of myocardial infarction: implications for practice. Heart 2006; 92:21–26,*[29] *with permission.)*

Reperfusion therapy should be considered for all patients presenting within 12 hours of onset of STEMI.[18,30]

Both primary PCI and fibrinolysis are proven treatments for STEMI, maximal benefit being achieved when they are given early. The timeliness of reperfusion treatment is a strong predictor of overall mortality.

Box 20.4 Typical indications for reperfusion therapy in acute myocardial infarction

Reperfusion therapy
Presentation ≤12 hours with ACS, unrelieved by GTN, *and*

New ST segment elevation in 2 or more contiguous leads with the cut-off points:
≥2 mV in men, >0.15 mV in women in leads V_2–V_3 and/or
≥1 mV in other leads, *or*
New-onset LBBB (include presumed new-onset), *or*
Posterior infarction (dominant R wave and ST depression ≥2 mV in V_1–V_2), *or*
Presentation 12–24 hours after onset of ACS with continuing pain and evidence of evolving infarction

Posterior myocardial infarction is an important presentation of STEMI where STE is not present in standard chest leads. STEMI (2–4% of cases) may present with new, presumednew LBBB although many patients who present with LBBB will not have an occluded culprit artery perhaps favouring PCI over thrombolysis.
Neeland IJ, Kontos MC, de Lemos JA. Evolving considerations in the management of patients with left bundle branch block and suspected myocardial infarction. J Am Coll Cardiol 2012;60(2):96–105.[24]

Age is strongly related to mortality in MI, often reflecting co-morbid illness.[28] Although elderly (>75 years) patients may receive a smaller relative mortality reduction than younger patients (<55 years), high baseline mortality in the elderly sees a threefold increase in lives saved (34 lives per 1000 treated versus 11 per 1000 in younger).[34]

Restoration of patency reduces infarct size, preserves LV function, reduces mortality and prolongs survival.

Strategies to achieve reperfusion can include:

- PCI (e.g. angioplasty with or without stent insertion)
- fibrinolytic (thrombolytic) therapy
- urgent CABG.

PRIMARY PERCUTANEOUS TRANSLUMINAL CORONARY INTERVENTION

- Primary PCI is far superior to thrombolytic therapy when delivered in centres of excellence and without delay with reduced short-term mortality (5.3% versus 7.4%), non-fatal re-infarction (2.5% versus 6.8%) and stroke (1.0 versus 2.0%).[35,36] TIMI-3 flow may be restored in 95% of patients compared with 54% after thrombolysis.
- The survival benefit of primary PCI compared with thrombolytic therapy is of the order of 20 extra lives saved per 1000 patients treated.[35] These benefits are not uniform and are significantly influenced by its better outcomes in high-risk patients (heart failure, cardiogenic shock, elderly, late presentations).

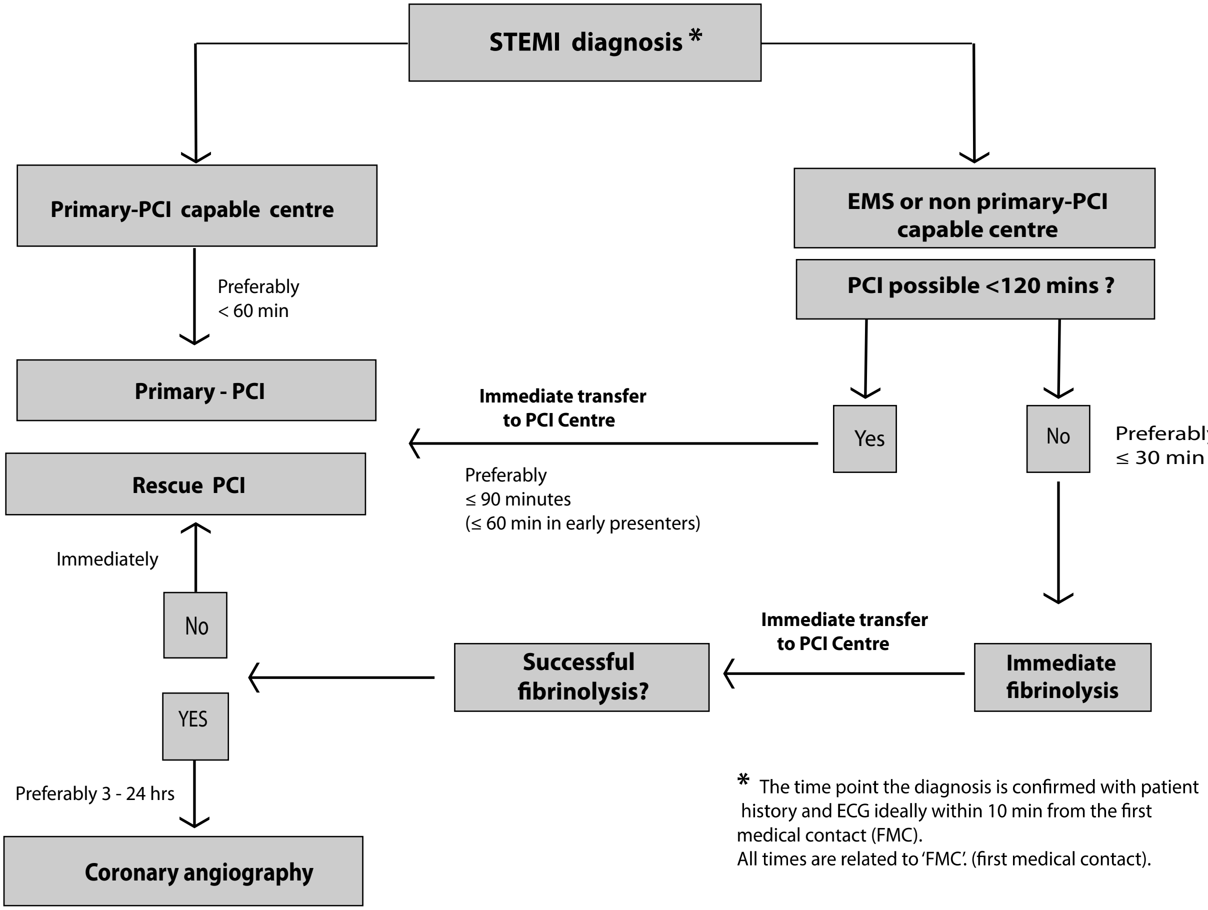

Figure 20.10 Prehospital and in-hospital management and reperfusion strategies within 24 h of FMC. Cath=catheterisation laboratory; EMS=emergency medical system; FMC=first medical contact; PCI=percutaneous coronary intervention; STEMI=ST-segment elevation myocardial infarction. *(Steg P.G., James SK, Atar D, et al. ESC Guidelines for the management of acute myocardial infarction in patients presenting with ST-segment elevation: The Task Force on the management of ST-segment elevation acute myocardial infarction of the European Society of Cardiology (ESC). Eur Heart J, 2012.* ***33****(20):2569–619. doi:10.1093/eurheartj/ehs215. Modified with permission of Oxford University Press (UK) © European Society of Cardiology.)*

Emergency PCI can be divided into:

- primary PCI
- pharmaco-invasive therapy (pharmacological perfusion followed by PCI)
- rescue PCI after failed pharmacological reperfusion.

Urgent PCI in STEMI is strongly indicated (level 1 evidence) in patients with:[18,30]

- presentation to cardiological centres of excellence
- contraindications to thrombolysis
- high risk but with predicted small or moderate benefit from thrombolytic therapy (e.g. elderly, diabetic and with presentation beyond 3 hours)
- cardiogenic shock even up to 12–36 hours after infarction[37] (see Ch. 24)
- failed thrombolysis
- previous CABG.

Very few patients have contraindications to PCI, the major risk factor being complications from adjunctive antiplatelet or antithrombin therapy. Caution is needed in those at risk of contrast-associated renal failure.[38,39] Primary PCI is limited by the risk of abrupt vessel closure (early) and late stenosis. Coronary stenting is superior to balloon angioplasty in preventing restenosis although survival and re-infarction benefits are less than in elective stent procedures.[13,40]

THROMBOLYTIC THERAPY

Thrombolytic therapy retains an important role in the acute treatment of STEMI because prompt access to PCI cannot always be provided.

- Thrombolytic therapy versus non-reperfusion treatment for STEMI results in significant mortality reduction (10.9% versus 13.4%; RRR 19%), a saving of approximately 20 lives per 1000 patients treated.[18,23]
- Outcomes are critically dependent upon time from symptom onset to administration. A goal after hospital arrival is 'door to needle time' of less than 30 minutes. Prehospital thrombolysis in highly selected patients is associated with reduced mortality compared with in-hospital thrombolysis (17% RRR).[30]
- Largest benefits are seen in anterior infarction (3.7% absolute mortality reduction), and less in inferior infarction (0.8% reduction).[23,41]

Thrombolysis within 6 hours of symptom onset prevents 30 deaths per 1000 patients treated; within 7–12 hours, 20 deaths per 1000 patients treated are prevented. There is no overall benefit for therapy beyond this time. Up to 40 deaths per 1000 could be prevented (RRR 50%) if treatment was given in the first hour.[23]

Thrombolytic agents (fibrinolytic agents)

Fibrinolytic agents (plasminogen activators) are divided into two major groups:

1. *Non-fibrin-specific:* these catalyse systemic fibrinolysis (e.g. streptokinase).[42]
2. *Fibrin-specific:* these produce limited plasminogen conversion in the absence of fibrinogen. Current agents include alteplase (tPA), reteplase (r-PA) and tenecteplase (TNK).

Disadvantages of fibrinolytic agents include that they take 30–45 minutes on average to reperfuse an occluded artery and complete reperfusion is achieved in only 60% of patients.

Development has sought to introduce agents that are more fibrin specific (more direct anti-thrombus action and induce less systemic fibrinolysis), have more resistance to plasminogen-activator inhibitor, or have a longer half-life (TNK) allowing bolus rather than infusion administration and with an acceptable rate of bleeding. Secondary fibrinolytic agents developed (t-PA) gave better patency rates than streptokinase and usually became the 'control arm' for subsequent trials.

Fibrin-specific agents (TNK, alteplase, reteplase) are recommended over non-fibrin-specific agents. Their shorter duration of action generally requires the concomitant early administration of UFH or LMWH.[30]

Major and minor contraindications are shown in **Table 20.2**.

Side-effects and choice of agent[30,38]

Bleeding complications are the most serious and important complication of thrombolysis. About 1% of patients may suffer an early cerebral haemorrhage. Risk factors are advanced age, significant admission systolic and diastolic hypertension, female gender, prior cerebrovascular disease and low weight. Major non-cerebral bleeds that require transfusion or significant intervention may occur in 4–13% of patients.

Failure to adjust the dose of fibrinolytic correctly to body weight may be associated with increased mortality and intracerebral haemorrhage.[38,39]

PRIMARY PCI VERSUS THROMBOLYTIC THERAPY

Despite the advantages of PCI over thrombolysis, many patients present to centres that do not offer primary PCI. Given the advantage of PCI over thrombolysis, the benefit of transfer to such a centre can be significant. Well-developed systems need to be in place to minimise transport delays.[30,40]

- Patients best suited for transfer for PCI are STEMI patients with high-risk features, those with high bleeding risk or other contraindications to

Table 20.2 Contraindications and cautions for fibrinolytic use in myocardial infarction (advisory following clinical consideration)

ABSOLUTE	RELATIVE (ADVISORY FOLLOWING CLINICAL CONSIDERATION)
• Previous haemorrhagic stroke • Other stroke or cerebrovascular accident ≤6 months • Intracranial neoplasm • Active internal bleeding ≤2 weeks (menses excluded) • Aortic dissection, known or suspected	• Severe uncontrolled hypertension on presentation (≥180/110 mmHg) • Oral anticoagulation therapy (INR > 2.5); known bleeding diathesis • Recent major trauma, surgery (≤4 weeks) including head trauma • Previous allergic reaction to drug to be used • Traumatic CPR • Active peptic ulcer disease • Pregnancy • Recent streptokinase; use different agent (risk of allergy, antibodies may reduce effectiveness) • History of prior CVA or intracerebral pathology not covered in contraindications • Chronic hypertension

PCI is generally the desired treatment in all of the above. INR=international normalised ratio; CPR=cardiopulmonary resuscitation; CVA=cerebrovascular accident.

Specialist advice should be sought urgently where doubt exists and PCI is not available. Patients with contraindication may still benefit from urgent PCI and indeed it is usually the preferred option.

fibrinolytic therapy or those presenting late (more than 3 hours after onset of symptoms).[38,43]

- Patients best suited for fibrinolytic therapy are those who present early and with low bleeding risk given that deleterious delays in reperfusion may worsen outcome. Current results from thrombolytic therapy in patients presenting early (<3 hours post onset) are very good as fresh clots seem more likely to be lysed.

The duration of symptoms and the time to achieve transfer are important modulating factors.[38,43] The advantages of more reliable revascularisation from PCI can be lost for many if transfer is not expedient and if delay is longer than 60–120 minutes.[38,43,44] The significance of transfer for an individual patient will vary significantly depending upon baseline risk.

Invasive strategy (PCI) is clearly superior to thrombolysis if:[18]

- ineligible for thrombolytic therapy
- cardiogenic shock or severe heart failure
- haemodynamically significant ventricular arrhythmias
- skilled PCI lab is available with surgical back-up:
  - medical contact-to-balloon or door-to-balloon is <90 minutes
- transfer can be achieved in <120 minutes and ideally <60 minutes
- diagnosis is uncertain not definite (e.g. ABS, myocarditis, pericarditis).

Other indicators that transfer to an expert centre for PCI should be considered are:

- high risk from STEMI
- age >75 years. PCI benefit over thrombolysis may be 1% at age 65, 6.9% at age >85[34]
- extensive anterior infarction with late presentation
- high risk of bleeding
- previous MI or CABG
- Killip class (see Table 20.4) is ≥3
- late presentation
- symptom onset was > 3 hours ago.

Fibrinolysis may be preferred if:[18,30,38]

- transfer to a centre for PCI may be harmful to patients where:
  - early presentation (3 hours from symptom onset and delay to invasive strategy)
  - invasive strategy is not an option (e.g. catheterisation lab occupied, not available)
  - delay to invasive strategy (e.g. prolonged transport time with delay likely greater than 60–120 minutes).

COMBINATIONS OF PCI AND THROMBOLYSIS[18,33,38,40,45]

Lack of universal access to acute PCI infarction requires many patients to receive fibrinolytic treatment. Given that urgent PCI is generally superior, various studies have been performed to provide PCI soon after fibrinolysis or to give fibrinolytic or other therapy to provide a bridge until PCI is available.

- There is little evidence that routine *immediate* PCI after fibrinolysis (<2–3 hours) confers benefit. Indeed this approach appears to be harmful.
- It is reasonable to transfer all patients following fibrinolytic therapy to a PCI-capable centre in anticipation of possible inadequate reperfusion as up to 20% who achieve reperfusion may re-infarct (see Fig. 20.10).[30] Repeat fibrinolytic therapy does not appear to provide benefit.
- Urgent PCI where there is evidence of failed reperfusion ('rescue PCI') has been shown to reduce re-infarction and heart failure with a tendency to improved survival.[46] Up to 40–50% of STEMI patients treated with fibrinolytics may have evidence of suspected inadequate reperfusion (ongoing STE or, less reliably, ongoing chest pain). Most benefit from rescue PCI is likely seen in patients with large myocardium at risk, those who remain haemodynamically unstable or in cardiogenic shock. Case-by-case assessment is required.
- Facilitated thrombolysis and pharmaco-invasive therapy[40,47] is a strategy of thrombolysis (full or adjusted dose) or significant antiplatelet or anticoagulant therapy followed as soon as possible by PCI (on site or after rapid transfer) regardless of whether there is evidence of failure to reperfuse. Results are variable.

ADJUNCTIVE THERAPY USED WITH REPERFUSION TREATMENTS (**FIG. 20.11**)

Early adjunctive therapy is necessary after thrombolysis as about 50% of patients fail to obtain or sustain coronary artery patency. The underlying artery remains unstable, evidenced by angiographic reocclusion in 30% and recurrence of ischaemia in 20%. Coronary arteries that have been dilated or have undergone stenting may similarly remain unstable.

Adjunctive therapies in the short term will thus largely be directed at platelet aggregation and the coagulation cascade in an attempt to decrease vessel or stent thrombosis. Therapies may also be directed at 'plaque stabilisation', myocardial ischaemia and arrhythmias. Improvement in adjunctive or supportive reperfusion therapies has been the major driver of improved outcomes from reperfusion strategies.

Compliance with guidelines for administration of these therapies significantly improves outcomes.

ASPIRIN AND CLOPIDOGREL

All patients undergoing reperfusion therapy for STEMI (PCI or fibrinolysis) should be given dual anti-platelet therapy (DAPT, aspirin and an ADP blocker, commonly aspirin and clopidogrel) unless contraindicated.[30,33]

Aspirin is one of the most significant and cost-effective treatments for STEMI. It prevents synthesis of

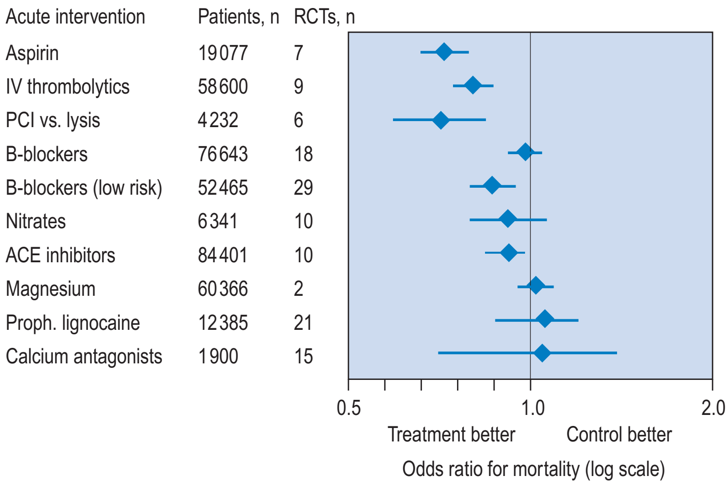

Figure 20.11 Effect of acute (early) adjunctive interventions upon mortality following MI. Results are from meta-analyses and various trials. Urgent percutaneous coronary intervention has not been compared to placebo but offers superior results to thrombolysis when performed at PCI centres within appropriate time frames. Beta blockers should only be used after exclusion of contra-indications. ACE=angiotensin-converting enzyme; RCT=randomised controlled trial; PCI=percutaneous coronary intervention.

thromboxane A_2, a potent stimulator of platelet aggregation and vasoconstriction. Given acutely in the ISIS-2 study it reduced absolute mortality by 2.4% (RRR 23%) and gave a nearly 50% RRR in re-infarction and stroke. It was comparable to the benefit from streptokinase and the combination had an additive benefit.[41,48] Treatment for a mean duration of 1 month resulted in approximately 25 fewer deaths and 10–15 fewer episodes of non-fatal re-infarction and non-fatal stroke for every 1000 patients treated.[48] It does not appear to increase bleeding and benefit is still present after 10 years. Similar benefit from aspirin is seen in patients who do not receive reperfusion.[39]

Clopidogrel confers significant additional benefit to patients who have received fibrinolytic therapy. Given in conjunction with thrombolytics and aspirin, it reduces the risk of early vessel reocclusion without a significant rise in bleeding. Clopidogrel added to aspirin and continued in patients not undergoing reperfusion therapy also lowered mortality rate (7.5% vs 8.1%) and the composite of death, re-infarction or stroke (9.2% vs 10.1%, 9 less events per 1000 patients). Benefit from this DAPT therapy is present across a wide range of MI severity and age groups and bleeding is not significantly increased.[39,43,49,50] Substitution of prasugrel or ticagrelor for clopidogrel following fibrinolysis is not currently advocated.[30]

DAPT is strongly indicated in STEMI patients undergoing primary PCI. Patients who undergo PCI and have a stent inserted benefit if they have received clopidogrel. Benefit is less evident in patients who undergo PCI but do not have a stent placed, and bleeding is problematic.

Newer ADP inhibitors such as prasugrel and ticagrelor have more rapid onset and predictable pharmacology than clopidogrel and are increasingly preferred. Caution is advised where there is increased risk of bleeding (advanced age, previous CVA, low body weight, liver disease) or need for CABG.

GLYCOPROTEIN IIB/IIIA INHIBITORS

Glycoprotein IIb/IIIa inhibitors (GPIs) include abciximab, eptifibatide and tirofiban and were particularly useful when stents were being placed. They have largely been replaced in the treatment of acute STEMI by P2Y12 antiplatelet agents. They may still retain some role in STEMI where a stent is to be placed, the lesion is complex, the patient is haemodynamically unstable and the absorption of oral agents is uncertain.[43,51,52] Historical trials of GPIs in combination with full-dose thrombolytics found increased bleeding. Trials in combination with half-dose thrombolytics were also disappointing, with increased bleeding (especially in the elderly) but no survival benefit. In STEMI patients who do not receive reperfusion therapy, GPIs do not appear to confer benefit.[39,43,50,52]

UNFRACTIONATED HEPARIN (UFH, STANDARD) AND LOW-MOLECULAR-WEIGHT HEPARIN

Antithrombin therapy is generally given in combination with PCI or with fibrin-specific fibrinolytic agents. Exposed or ruptured plaque leads to activation of thrombin.

The net benefit-to-risk ratio of using thrombin inhibitors in MI is not clear, however. Prior to the use of fibrinolytics and aspirin, a limited number of small trials suggested that UFH reduced mortality (from 13.1% to 9.2%, 20–25% RR reduction) but patient numbers were small. With the introduction of fibrinolytics and aspirin, UFH administration was continued, reflecting the basis on which the drugs were trialled and licensed. Heparin effect seemed to be more modest in this setting. Few trials (1239 patients) examined whether UFH added survival benefit to patients already treated with both thrombolytics and aspirin. At most, UFH benefits seems to be small (perhaps 5 lives saved per 1000 patients treated) and bleeding can be problematic.[39,41,53] UFH has been the comparator in studies of LMWHs. Four anticoagulants are

currently used clinically (UFH, LMWH, bivalirudin and fondaparinux).

Current recommendations thus are:

- Patients undergoing thrombolysis with fibrin-specific agents require an anti-thrombin agent for 24–48 hours. Weight-adjusted intravenous UFH is still used but there has been a strong shift to the use of LMWH (e.g. enoxaparin).[38,53–56] Meta-analysis suggests an advantage of enoxaparin over UFH. Among STEMI patients treated with enoxaparin, approximately 21 deaths or MI events were prevented for every 1000 patients, at the cost of an increase of 4 non-fatal major bleeds.[55] Clinical assessment of bleeding risk may still affect treatment.[38] Streptokinase-treated patients usually receive heparin only when there is a high thromboembolic risk. Fondaparinux may be an alternative agent in non-PCI STEMI treated patients.
- LMWH (preferred) or UFH are recognised treatments for STEMI patients undergoing primary PCI.[30] There is evidence that intravenous enoxaparin (0.5 mg/kg) is superior to UFH with lower mortality and less bleeding.[30,57]
- Bivalirudin (a direct antithrombin inhibitor) is an alternative treatment for primary PCI in STEMI.[30,57]
- Fondaparinux (pentasaccharide factor Xa inhibitor) is associated with a peculiar problem of end-catheter thrombosis during PCI requiring concomitant use of intravenous enoxaparin and is not recommended for primary PCI in STEMI.[30,57]
- UFH or LMWH or fondaparinux administration is indicated in patients who present late or cannot undergo reperfusion therapy.

BETA BLOCKERS[30,33,58]

Pre-thrombolysis era trials demonstrated benefit from early beta-blocker therapy (intravenous and oral) leading to their aggressive use. Post-thrombolysis trials have demonstrated less benefit and even harm in some patient groups.[18,33,58] Early intravenous beta-blocker therapy in acute MI reduces the risk of re-infarction and VF, but increases the risk of early cardiogenic shock with increased mortality (COMMIT Study).[58] There is substantial net hazard in haemodynamically unstable patients and moderate net benefit in those more relatively stable patients.[58] They are best avoided but may have a role for the targeted treatment of specific problems such as hypertension or tachycardia, although it is wise to assess LV function, perhaps with echocardiography.

- Patients with MI who have contraindications such as pulmonary oedema, shock, hypotension, bradycardia, advanced atrio-ventricular block or asthma[18,30,33] should not receive early beta blockade.
- Haemodynamically stable patients should commence oral beta blockers within 24 hours of the onset of symptoms, introduction being gradual or delayed for 24 hours if there is concern.

OTHER THERAPIES

Although the initial doses of ACE inhibitor may cause hypotension, the early introduction of ACE inhibitors (within the first 48 hours of STEMI) is generally well tolerated and is associated with a small reduction in 30-day mortality, this being evident in the first week.[30] Nitrates may be beneficial for the treatment of recurrent angina, but may be harmful if hypotension occurs or prevents the use of more proven therapies such as ACEI or beta blockers. Glucose–insulin–potassium therapies have not been shown to provide ‘cardio-protection’ and complicating hyperglycaemia, hypokalaemia and fluid gain may be harmful.

COMPLICATIONS OF MI

ARRHYTHMIAS[30] *(SEE CH. 22)*

Rhythm disturbance occurs in nearly all patients following acute MI and is most likely within the first few hours of onset and during reperfusion. There has been a decline in the incidence of VF from approximately 4.5% of admissions to 1% of admissions with MI. Post-MI arrhythmias are best prevented by rapid revascularisation, maintenance of electrolytes and treatment of heart failure.

- Correct hypoxia, hypovolaemia or acid–base disturbances.
- Maintain serum potassium in the normal range (4.0–5.0 mmol/L).[18,59]
- Maintain the serum magnesium level.

Prophylactic beta blockers reduce the incidence of VF. Prophylactic lidocaine is associated with increased mortality and is reserved for the treatment of life-threatening ventricular arrhythmias. Prophylactic or routine i.v. magnesium is not of proven value.[18] Asymptomatic ventricular arrhythmias do not necessarily benefit from intervention.

POSTINFARCTION ANGINA AND REINFARCTION[8,26,30]

Postinfarction angina (STEMI or NSTEMI) usually results from decreased myocardial oxygen supply due to re-occlusion or spasm of a transiently patent coronary artery. It is usually an indication for consideration of revascularisation. Ischaemia may occur in the infarct related or other vessels and if severe may result in infarct extension. Simple factors such as tachycardia, hypertension, anaemia and fever should be corrected and aggressive treatment with antiplatelet agents, nitrates and beta blockers is indicated. Ongoing pain with ECG changes is indicative of high risk. Insertion of an intra-aortic balloon pump may help improve symptoms, minimise ischaemia and may bridge for

Table 20.3 Mechanical complications of myocardial infarction

	CVP	PAOP	CO	OTHER FINDINGS ON PAC	ECHOCARDIOGRAPHY
Mechanical complications					
Free wall rupture	↑	↑	↓↓	Usually tamponade physiology: RA mean, RV and PA end-diastolic, and PAOP pressures are elevated and within 5 mmHg (0.665 kPa) of one another	Pericardial effusion with tamponade and RV diastolic collapse; may visualise pseudoaneurysm
Acute ventricular septal defect	↑	↑	↓↓	Left-to-right shunt with oxygen step-up at RV level; V waves may be seen in PAOP tracing	Visualisation of left-to-right shunting with colour Doppler, can sometimes visualise defect as well
Acute mitral regurgitation	↑↑	↑↑	↓↓	V waves in PAOP tracing	Regurgitant jet apparent on colour Doppler; can diagnose papillary muscle rupture with flail leaflet
RV infarction	↑↑	↓ or normal	↓↓		RV dysfunction
Pump failure (cardiogenic shock)	↑↑	↑↑	↓↓		Decreased overall LV performance; regional wall motion abnormalities; dyskinetic or aneurysmal segments may be seen

Echocardiography has largely replaced the need for insertion of a pulmonary artery catheter although information for a PAC shown here is useful in understanding physiology. Coronary angiography and studies may be required to determine coronary anatomy and may provide additional data.
CVP=central venous pressure; PAOP=pulmonary artery occlusion pressure; CO=cardiac output; PAC=pulmonary artery catheterisation; RV=right ventricle; RA=right atrium; PA=pulmonary artery.

further PCI or CABG. Re-infarction in the 10 days following STEMI occurs in up to 5–10% of patients.

*CARDIAC FAILURE (SEE CH. 24) AND CARDIOGENIC SHOCK (**TABLE 20.3**)*[13,18,30,37,60,61]

There is a strong association between severity of LV dysfunction post MI and prognosis, well defined by the use of the Killip classification (**Table 20.4**).[62–64] LV dysfunction with the clinical signs of failure occurs in up to 30–40% of patients post STEMI and is associated with a mortality of 20–40%. It usually develops when the abnormally contracting segment exceeds 30% of the LV circumference: cardiogenic shock or death results when it exceeds 40%. It is more common in the setting of previous infarction, and is associated with a poor short- and long-term prognosis. With large MI there is progressive thinning of affected myocardium, with stretching and dilatation of the ventricle, and sometimes frank aneurysm formation. Goals of treatment are:

- correction of hypoxia
- clinical and echo-guided fluid therapy; avoidance of anaemia
- preload reduction with diuretics and nitrates; inotropes if needed
- avoidance of negative inotropes including beta blockers
- measured introduction of ACE inhibitors
- clinical determination as to whether they should follow a 'cardiogenic shock pathway'.

Table 20.4 Killip classification of severity of infarction based on clinical assessment and its correlation with hospital mortality in 1967[64] and 30-day mortality in 1993[63]

KILLIP CLASS		CASE FATALITY (%) KILLIP & KIMBALL[64]	CASE FATALITY (%) GUSTO[63]
Class 1	No failure	6	5
Class 2	Mild to moderate heart failure (S3, rales <50% lung fields)	17	14
Class 3	Severe heart failure (S3, rales >50% lung fields)	38	32
Class 4	Cardiogenic shock	81	58

There is a strong correlation between the degree of left ventricular dysfunction and mortality in ACS.
Reproduced from Thompson P. Coronary Care Manual, 2nd edn, with permission.[62]

Angiotensin-converting enzyme (ACE) inhibitors appear to limit dilatation, preserve LV function and improve prognosis. Benefits are maximal in those with poor LV function. ACE inhibitors are thus recommended for all patients with significant LV dysfunction and are usually started early following MI.

Cardiogenic shock complicates up to 10% of STEMI and also 2–3% of NSTEMI. Although sometimes present on admission, it often does not arise for some hours. Mortality from cardiogenic shock remains very high (55–70%) and is the major cause of hospital mortality from STEMI. The presence of shock is usually evidenced by:

- SBP <90 mmHg (11.97 kPa) or a significant fall from baseline
- cardiac index <2.2 litres/min/m^2 after correction of hypoxia and hypovolaemia
- evidence of tissue perfusion (metabolic acidosis, oliguria, confusion).

In patients who manifest cardiogenic shock, 10% arrive at hospital in shock, but 90% develop it after hospitalisation. More than 60% have at least 75% stenosis of all three coronary arteries including the LAD.[60] Patients may have 'stunned' myocardium that is capable of improvement with revascularisation and initial intensive medical support. Revascularisation with PCI or CABG is preferred to thrombolysis and medical management; the benefits are still present beyond 5 years (survival 32.8% vs 19.6%).[37] Many patients require intubation and ventilation for management. Cardiac support therapy may include balloon counterpulsation and support with inotropes that may include dobutamine, milrinone and levosimendan.

The presence of right ventricle infarction[61] should be considered in any patient with inferior MI (review lead V_4R and echocardiogram). It is associated with significantly increased mortality. In its severest form, it is a cause of cardiogenic shock.[61] The triad of hypotension, clear lung fields and elevated JVP is seen in only 25% of patients. Treatment principles are different to those for LV dysfunction. Patients with RV infarction often require:

- volume loading and maintenance of filling pressures (clinical and echo assessment); diuretic therapy, afterload reduction and unrecognised hypovolaemia may aggravate hypotension and renal insufficiency in these patients
- maintenance of atrioventricular synchrony by aggressive treatment of atrial fibrillation and consideration of atrial and ventricular lead placement when pacing is required
- inotropic therapy.

Although 80% of cases of cardiogenic shock are due to extensive myocardial necrosis, mechanical complications including mitral regurgitation, ventricular rupture, tamponade and myocardial rupture may be causative. The different physiology of these causes is outlined in Table 20.3.

MITRAL REGURGITATION (MR)[18,65,66]

Transient functional mitral regurgitation is common after MI, LV wall dysfunction causing modification of the subvalvular apparatus and incomplete closure of the valve. This may be asymptomatic and silent detected in up to 30% of patients on echocardiography or may be associated with a soft murmur. Catastrophic papillary muscle rupture, usually 1–4 days post MI, may be associated with mortality of 75–95%, better haemodynamic tolerance being present in incomplete ruptures. Posterior leaflet rupture is most common as it receives its blood supply from the dominant coronary artery (usually the RCA), whereas the anterior leaflet has a dual blood supply. The infarction may be small and localised. A decrescendo systolic murmur may be present rather than the typical pansystolic murmur of chronic regurgitation; however, murmurs may be soft owing to equalisation of pressures between the LV and left atrium with severe regurgitation.[30]

MR can complicate even relatively small MI and the diagnosis should be considered in shocked patients, particularly women and those with NSTEMI, inferoposterior MI and pulmonary oedema.[66] Catastrophic MR requires surgery. Non-surgical and surgical mortality are high. Pharmacological and mechanical afterload reduction often provides a bridge. Where MR is severe and concomitant CABG is required, surgery is indicated. Where MR is significant but CABG is not required, the value of surgery is less certain.[65]

CARDIAC RUPTURE[10,18,30,67,68]

Rupture of the interventricular septum occurred historically in 1–2% of MI, but has fallen to an incidence of 0.2% in the post-thrombolysis era, usually in large infarctions (60% of cases). Anterior and inferior infarctions are equally represented and single-vessel disease is not uncommon. It is often heralded by a new long systolic murmur, which initially may be soft or absent and the patient may not be haemodynamically compromised; 22% may have had silent infarction. Diagnosis is best confirmed by echocardiography, helping to exclude the differential diagnosis of mitral valve rupture. Almost always there is progressive clinical deterioration (untreated mortality of 54% at 1 week and 92% at 1 year). Surgical repair is considered as soon as the diagnosis is made; intra-aortic balloon counterpulsation often provides a bridge to surgery. LV free wall rupture is usually catastrophic, resulting in pulseless electrical activity and death. Subacute rupture (leaking blood is contained by pericardium forming a false aneurysm) is less common and may mimic re-infarction. It requires urgent detection and surgery. Risk factors are advanced age, first infarction (lack of fibrosis) and acute hypertension, but chronic hypertension may be protective (hypertrophy).

SYSTEMIC EMBOLI[10,69]

Embolic (ischaemic) stroke occurs in approximately 1% of patients during their hospital admission and in 2% by 12 months. Most of these cases occur following extensive anterior MI.

- 30–40% of anterior Q-wave MIs may be complicated by mural thrombus (echocardiography). Embolisation is most frequent with large or protruding emboli and is uncommon following inferior infarction.
- 5–10% of these may undergo embolisation, usually within the first 10 days.

Anticoagulation therapy is usually recommended for ≥3 months (initial heparin, then warfarin) if mural thrombus is proven or if there is extensive anterior regional wall motion abnormality. Clinicians should have a high index of suspicion in the presence of large anterior infarction and routine echocardiography is recommended. Patients with poor LV function remain at long-term risk of embolic stroke. Current guidelines recommend continuation of warfarin for 3 months; however, the major impact on stroke prevention appears to result from optimisation of cardiovascular risk factors such as hypertension and lipids.[69]

POST-MI INJURY SYNDROME (DRESSLER'S SYNDROME) AND PERICARDITIS

A pericardial rub may develop 24–72 hours after large, usually anterior MI. Associated pain may mimic ischaemia and biomarkers and echocardiography may be useful in excluding post-infarction angina. Small pericardial effusions may be present. Dressler's syndrome is a now uncommon, later-presenting pericarditis thought to be an immunopathic response to myocardial necrosis. It is characterised by fever, pleuropericardial pain and rub, arthralgia and elevated inflammatory markers.

MANAGEMENT OF UNSTABLE ANGINA AND NSTEMI (NSTEACS)

NSTEACS often result from the development of non-occluding thrombus upon unstable plaque. Superimposed vasospasm and microembolisation may aggravate myocardial ischaemia. Therapies are directed at 'white thrombus' and plaque stabilisation, and at reduction of myocardial oxygen demand.

General principles of treatment are:

- immediate pharmacological relief of ischaemic symptoms
- immediate introduction of antiplatelet therapy, usually in conjunction with an antithrombin agent, to stabilise plaque white thrombus and prevent complete artery occlusion
- assessment of benefits of early invasive versus medical therapy (early PCI).

Thrombolytic agents are generally contraindicated in the treatment of NSTEACS; their routine administration is associated with poorer outcome.[23]

The causes of NSTEAC vessel instability and the cause of ischaemia are far more diverse than those of STEMI. Accordingly the results of interventions are far more diverse. Treatment decisions and their risk–benefit are often guided by scoring systems.

EARLY INVASIVE VERSUS MEDICAL THERAPY IN NSTEACS[8,26]

Although medical therapy is introduced to all patients, keen observation should be continued for signs of instability that suggest an invasive approach is appropriate. Prior to the introduction of potent antiplatelet inhibitors as 'upstream therapy' and coronary stents, early invasive strategies were associated with minimal benefit or with adverse outcome despite their theoretical attractiveness. The development of better adjunctive agents (principally GP inhibitors) has led to the recognition that early invasive strategies are associated with reduced rates of MI and death in many groups.

Scoring systems are available to guide therapy. They are ideally based on simple and readily available clinical information. The GRACE and TIMI risk scores predict both in-hospital and post-discharge 6-month mortality.[25,28]

The benefits of PCI are dependent upon the baseline risk to the patient. Emergent PCI is demonstrated to offer clinical benefit to patients with high-risk features such as elevated troponins, recurrent chest pain and recurrent ECG changes.

ANTI-ISCHAEMIC AGENTS

- Sublingual *nitrates* (300–600 μg usually given in two doses at least some minutes apart) may provide immediate relief of symptoms. Where pain or ECG changes are ongoing, nitrate infusions produce better pain control and decrease of ST-segment depression, suggesting lessening of ischaemia.[8] Clinical features determine dosing.
- *Beta blockers* require similar precautions to those outlined in the treatment of STEMI and intravenous beta blockade again should only be targeted to specific goals (e.g. control of tachycardia, hypertension). Long-term oral beta blockade is likely to be a mainstay of therapy.
- *Calcium channel blockers* (non-hydropyridine agents such as diltiazem or verapamil)[26] may provide symptom relief of recurrent ischaemia when beta blockers and nitrates have been fully used or where there are contraindications to beta blockers. Left ventricular failure is generally a contraindication.

ANTIPLATELET THERAPIES

Antiplatelet therapy is the cornerstone of treatment in both the acute and long-term treatment of NSTEACS. It should be started as soon as the diagnosis of NSTEACS is suspected.

The current standard of care for such patients includes dual antiplatelet therapy (DAPT) usually with aspirin and an adenosine diphosphate (ADP)-receptor

antagonist, regardless of whether an invasive procedure is planned or not. It is indicated acutely and for 12 months after.

1. *Aspirin* has similar long-term benefits to those seen following STEMI and should be continued lifelong. Long-term low-dose (75–100 mg/day) is as effective as high-dose aspirin (300–325 mg/day) but is associated with lower rates of bleeding. Up to 10% of patients may have resistance to aspirin.[11]
2. *P2Y12-receptor antagonists* or *ADP receptor antagonists* include clopidogrel, prasugrel and ticagrelor. *Clopidogrel* (in combination with aspirin) was demonstrated in the 'CURE' study[70] to produce a 20% reduction in adverse events when commenced early and continued. Reduction was mainly in MI. Clopidogrel, however, has a slow onset of action that is then prolonged due to irreversible platelet binding. Some 4–30% of patients maintain significant platelet reactivity that is associated with risk of adverse cardiac events.[43,50,71] Newer *P2Y12* antagonists including *prasugrel* and *ticagrelor* do not require metabolic activation and also provide more extensive block. They show superiority to clopidogrel in PCI but at the expense of increased bleeding. They may be a preferred treatment where appropriate risk of stroke, advanced age and low weight is considered.[72] The role of these agents in non-PCI patients is under study but is likely to expand.
3. *GP IIb/IIIa inhibitors* include abciximab, tirofiban and eptifibatide. The more aggressive use of agents such as clopidogrel has seen their benefit decline. They probably retain some value in high-risk NSTEACS patients undergoing PCI. Given as 'medical treatment' they have not demonstrated significant benefit. Benefit is largely confined to patients undergoing PCI.[4,50] The direct antithrombin bivalirudin may provide similar benefits with lower risk of bleeding.

ANTITHROMBINS AND ANTICOAGULANTS[4,8,26]

- Anticoagulants are used in NSTEACS to inhibit thrombin production or activity and decrease thrombus complications.[4] Addition of UFH to aspirin therapy produces a significant reduction in recurrent angina, and subsequent MI.[73]
- Review of head-to-head studies of LMWHs compared with UFH show minimal difference between their outcomes (less difference than when used in STEMI).[73] Their simplicity, lack of need for monitoring and acceptable safety profile may favour their administration. They are generally preferred except perhaps where surgery is anticipated. Fondaparinux may also be used when a 'conservative' management approach is intended.
- Fondaparinux (requires bolus enoxaparin at time of PCI) and bivalirudin (requires concomitant heparin or antiplatelet therapy) are alternative anticoagulant treatments in NSTEMI patients undergoing an early invasive approach.

ONGOING AND DISCHARGE CARE OF ACS (SECONDARY PREVENTION) (FIG. 20.12)

A number of therapies have been studied in the long-term (secondary) treatment of ACS. These treatments are very similar for STEMI and NSTEACS:

1. *Aspirin:* is indicated at a dose of 100 mg per day unless there are contraindications and should be continued lifelong. In the first 2 years after MI, aspirin therapy results in an absolute decrease of approximately 36 vascular events (vascular death or non-fatal MI or stroke) for every 1000 patients treated.[48]
2. *Clopidogrel:* is generally continued throughout the hospital stay in both STEMI and NSTEMI.[33] Clopidogrel is generally continued for all STEMI patients without contraindications whether they

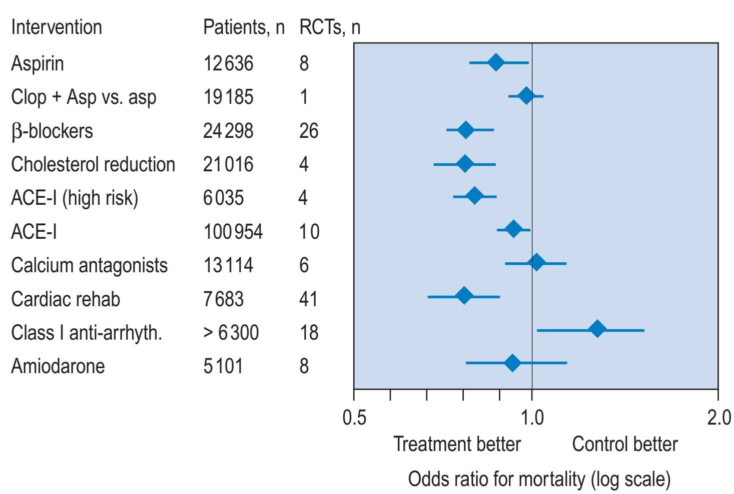

Figure 20.12 Late intervention in acute myocardial infarction. Effect of various adjunctive treatments continued following hospital discharge. Results are from meta-analyses and various trials. Treatments may confer benefit for both STEMI and NSTEACS. DAPT benefit is dependent upon the presence and nature of stents as well as background bleeding risk. ACE=angiotensin-converting enzyme; RCT=randomised controlled trial; Clop=clopidogrel; Asp=aspirin.

have received PCI, thrombolysis or no reperfusion therapy. Given in conjunction with aspirin, clopidogrel is proven to be of benefit when administered long term to patients at high risk of future cardiovascular events (the CURE study), although it is associated with an increased risk of bleeding. Clopidogrel is also a useful treatment in patients with aspirin resistance. Presence and type of stent may determine whether clopidogrel or a P2Y12-receptor antagonists is continued longer.

3. *Beta blockers:* administered orally following discharge they are associated with significant re-infarction and survival benefit.
4. *Inhibitors of the renin–angiotensin–aldosterone system (RAAS):* patients with anterior MI and ejection fraction <40% maintained on long-term ACE inhibitor therapy may experience a 20% sustained RR in mortality (that is additive to aspirin and beta blockers) and a significant reduction in the incidence of LV failure.[30,74] In patients intolerant of ACE inhibitors, an ACE receptor blocker may be used. Aldosterone antagonists such as spironolactone and eplerenone may also be used in patients with severe LV dysfunction but caution is taken in the setting of RAAS inhibitor use and renal dysfunction as severe hyperkalaemia may occur[30] (see Ch. 24).
5. *Lipid-lowering agents:* all patients with ACS should commence statins in hospital. Benefit is maximal (and not confined to myocardial events) in patients with elevated cholesterol and other risk factors, but benefit is present at all cholesterol levels. Intensive statin therapy has an advantage (lower all-cause mortality) over less-intensive lipid reduction. Commencement of statins within the first day has benefits over later commencement.[75]
6. *Other anti-ischaemia agents*: routine use of calcium channel blockers does not appear to reduce recurrent myocardial infarction nor decrease mortality. They may be of symptomatic use in patients intolerant of beta blockers or where there is a clinical need such as hypertension or arrhythmia.[30] Carvedilol may be of benefit in patients with ACS.
7. *Antiarrhythmic therapy:* this is not routinely continued. In the CAST study, prolonged flecainide therapy was used to suppress ventricular ectopy. Despite doing so, mortality was increased. Amiodarone in low doses (200 mg/day) may reduce mortality, but results of definitive trials are awaited and it has significant side-effects. It cannot currently be recommended as routine therapy. For patients with actual, or who are at high risk of, ventricular arrhythmia, consideration may be given to long-term amiodarone or use of an implantable defibrillator.
8. *Warfarin:* given alone or in combination with aspirin is associated with lower rates of a composite of 'death, re-infarction and thromboembolic stroke'. Concerns about bleeding (especially in the elderly) see its clinical application restricted.[76] Warfarin is useful for patients with severe ventricular dysfunction, atrial fibrillation or a prothrombotic tendency.[18]
9. *Lifestyle advice:* this is most important and all patients should cease smoking and receive advice on exercise and diet. Blood pressure control and appropriate treatment of diabetes are of high importance.[7,77]

MYOCARDIAL INFARCTION IN THE INTENSIVE CARE UNIT

Myocardial ischaemia is a common problem in the ICU. It also commonly complicates perioperative care of major surgery, with mortality of up to 15–25%. Of concern, studies have shown that a rise in troponin level following non-cardiac surgery is associated with significant 30-day mortality. The problem is what to do about this. Diagnostic criteria are uncertain but a system has been proposed by Devereaux et al.[78] There are few randomised controlled trials to guide therapy of postoperative infarction, or infarction complicating the care of the critically ill. Many patients with such presentations were excluded from trials of ACS therapy.

The pathophysiology of postoperative infarction and infarction in ICU patients is probably different to that of ACS.[79] Studies suggest that, in the presence of severe ischaemia, left main disease and triple-vessel disease are common and that ischaemia is secondary to oxygen supply-and-demand problems (Type 2 MI) rather than thrombosis. However, data on this are conflicting.[79] The absence of thrombosis as an underlying pathological mechanism in many suggests that standard aggressive 'antithrombus' therapies will have different risk–benefit profiles, and that harm is exacerbated by the often high bleeding risk of these patients.

The patient with significant STE and haemodynamic instability in the ICU presents a difficult problem. Echocardiography may be useful in providing information about RWMA and the amount of myocardium at risk. Thrombolysis is usually precluded by bleeding risk and by uncertainty regarding the causative process. Angiography will allow diagnosis and intervention if necessary; however, the use of adjunctive therapy (short- and intermediate-term) may be associated with significant bleeding. Reversible factors such as hypoxia, severe anaemia, anxiety and tachycardia must all be controlled where possible. Hypotension may limit the ability to administer beta blockers and control tachycardia.

APICAL BALLOONING SYNDROME ('TAKOTSUBO SYNDROME')[80–83]

Apical ballooning syndrome (ABS) characteristically presents as acute LV dysfunction usually triggered by emotional or physical stress. It usually presents with chest pain that can mimic ACS. Although there is no flow-limiting lesion precipitating ischaemia, the

biomarkers and ECG may suggest ischaemia. Echocardiography may display LVWMA affecting the apical and often the mid-ventricular region with sparing of the basal region. The hypercontractile basal myocardium can generate LV outflow tract obstruction.

Its presence is being increasingly recognised; 1–2% of patients presenting with an initial diagnosis of ACS are recognised to have ABS. Symptoms are like those of ACS and 1/3 have STE. Ninety per cent of patients are postmenopausal women, 70% have a clear emotional or physical trigger but only <3% are younger than 50 years. Diagnostic criteria have been devised, but management and the need for investigation are often clinically determined by the need to exclude vessel occlusion. Major complications in severe ABS include congestive cardiac failure, hypotension, cardiogenic shock, arrhythmia, LV thrombus and mitral regurgitation (systolic anterior motion due to outflow tract obstruction). Mortality may be 1–2%.

Treatment is usually supportive. Echocardiography will help determine if PCI is needed, this being preferable to thrombolysis. With regards to aetiology, elevated catecholamine levels related to severe stress are clearly implicated. A theoretically plausible, but unproven, theory is that there is a higher concentration of β-receptors in apical myocardium with decreasing levels from apex to base. There may be a resulting greater contractile response in apical myocardium than in basal myocardium whilst, paradoxically, high catecholamine levels may be negatively inotropic.[81]

BLEEDING COMPLICATIONS POST REPERFUSION THERAPY

The increased use of aggressive fibrinolytic regimens and of adjunctive reperfusion agents has led to troublesome bleeding in some patients. Many patients presenting for elective or emergent non-cardiac surgery have also been exposed to these agents. Some knowledge of reversal of these agents is necessary.[4,30,84]

1. *GPIIb/IIIa blockers*: abciximab, a chimeric monoclonal antibody, has a short half-life, but antiplatelet activity is still prolonged at 24–48 hours. Fortunately transfused platelets are not affected and will assist with bleeding reversal. The newer agents tirofiban and eptifibitide have very short half-lives when renal function is normal and antiplatelet action returns to normal 4–8 hours after discontinuation. During this period, however, antiplatelet action is profound. It is suggested that, at peak blood levels, administration of fresh frozen plasma (8 units) and platelets (2 units) is probably necessary to reverse antiplatelet action.[84]
2. *Clopidogrel*: it is recommended that clopidogrel and newer inhibitors be ceased at least 5 days before elective CABG, but this is not always possible in emergent surgery or in unstable cases. Major bleeding rates may approach 10% in these cases. Pharmacology suggests that platelet transfusions are necessary to moderate this but dose is unknown.[84]
3. *LMWHs:* reversal of LMWHs with protamine is variable and incomplete, even with doses of 100 mg. Protamine may reverse up to 60% of LMWH action. Although it may reverse 100% of the anti-IIa activity, it has far less effect on anti-Xa activity. It is suggested that doses of protamine should equal doses of enoxaparin administered on a milligram-per-milligram scale.[84]
4. *Fibrinolytic agents*: in the setting of life-threatening bleeding, large doses of cryoprecipitate (10–20 units) may be required to replete fibrinogen (target >1 g/L) and coagulation factors (especially factor VIII). Fresh frozen plasma may supplement factor V and VIII levels. Platelet transfusions at high dose may replace platelets and supplement factor V levels; ε-aminocaproic acid at a dose of 5 g (0.1 g/kg) over 30–60 minutes followed by continuous infusion (0.5–1.0 g/h) may assist with bleeding control. Fibrinolytic reversal carries the risk of culprit coronary artery reocclusion.[84]

OUTCOME OF MYOCARDIAL INFARCTION

The in-hospital mortality from acute MI has been steadily decreasing over the past three decades from 15% to 30% in the 1970s to approximately 10% in 1980 and now to around 8–9% in the new millennium.[2–4] Despite improved mortality, 60% of all deaths occur within the first hour (usually from VF), usually before reaching a medical facility.[4,36] Modern management of acute MI has undoubtedly contributed to decreased mortality. Further significant reductions in mortality must come from management strategies within the first hours of the onset of symptoms.

The major in-hospital changes are likely to come from:[3,30]

- better hospital organisation to increase access to PCI
- increased rates of PCI or thrombolysis in eligible patients
- increased use of adjuvant therapies and discharge medications.

The role of reperfusion therapy cannot be underestimated. In one study, the in-hospital mortality was 5.7% for those who received thrombolysis but 14.8% for those who were eligible for but did not receive such therapy (9.3% versus 18% in eligible women who did not receive therapy, 10.5% versus 19% in eligible elderly). Up to 24% of eligible patients do not receive reperfusion therapy.[3,36,44]

Adult cardiopulmonary resuscitation

Peter T Morley

The incidence and outcomes of cardiac arrests appear not to have changed dramatically over a number of decades. However, despite the appearance that outcomes from cardiac arrests are not improving, there are some bright spots where consistent improvement has been observed.[1,2] There are many potential reasons for these improvements, but the most likely are related to early detection, improved delivery of good CPR, and improved post-resuscitation care.

PREVALENCE AND OUTCOMES OF CARDIAC ARRESTS

Approximately 75% of deaths from cardiac arrests occur in the pre-hospital setting. Cardiac arrests in the community occur at approximately 50–150/100 000 person years.[3] The incidence of cardiac arrests is dramatically affected by the definition of the denominator (e.g. all cardiac arrests (89/100 000 person years) versus those with a presumed cardiac cause and where resuscitation was attempted (31/100 000 person years)[3]).

In-hospital cardiac arrests occur at approximately 1–5/1000 admissions,[4] with a similar denominator effect (as the majority of in-hospital cardiac deaths are expected and occur without attempts at resuscitation).

The majority of cardiac arrests in both pre- and in-hospital settings appear to be of cardiac origin, but the underlying causes, co-morbidities and presenting rhythms vary significantly between studies.

Outcomes of cardiac arrests are variable depending on the origin of the report, and are also critically dependent on the denominator.[3] The best outcomes from a cardiac arrest (near 100%) occur in the electrophysiology laboratory (where ventricular fibrillation (VF) is often deliberately induced). The outcomes from in-hospital cardiac arrest are surprisingly good (hospital discharge as high as 42%) despite significant co-morbidities, and are probably related to their early detection, the early arrival of the advanced life support team, and the detection and treatment of reversible causes.[5]

INTERNATIONAL REVIEW PROCESS

Since the formation of the International Liaison Committee On Resuscitation (ILCOR) in 1992, a cooperative international evaluation of the resuscitation science has resulted in the publication of international guidelines in 2000, and international consensus documents on resuscitation science in 2005 and 2010.[6] The process for the 2010 consensus on resuscitation science involved the review of 277 topics by 313 international contributors,[7] with the completion of 411 worksheets (available at www.ilcor.org). The published guidelines of the major resuscitation councils throughout the world (including the American Heart Association, and the European Resuscitation Council) are based on this consensus on science document. In 2010, Australasian guidelines were published,[8] cobadged by the Australian Resuscitation Council and the New Zealand Resuscitation Council, under the auspices of the Australian and New Zealand Council on Rescuscitation (ANZCOR).

The international science review process continues to be refined and a new consensus on resuscitation science document is planned for publication in 2015.

IMPORTANCE OF CHAIN OF SURVIVAL

The term chain of survival has been used to define the important links in the chain for the resuscitation process. The key links, which apply to both in- and out-of-hospital cardiac arrests, are: early recognition and the summoning of help, early basic life support, early access to defibrillation, and early advanced life support including post-resuscitation care.[6]

RECENT CHANGES TO GUIDELINES

As a result of the science review published in 2010,[6] a number of important changes have been made to the guidelines for both basic and advanced life support. In summary the basic life support changes include: commencing CPR where the victim is unresponsive and not breathing normally; commencing CPR with compressions rather than initial breaths; and an increased depth of compressions (>5 cm).[9] The advanced life support priorities include: focusing on the provision of good, uninterrupted CPR (including charging the defibrillator during compressions), and identifying reversible causes and specific circumstances where the standard ALS algorithm may need to be modified.[8,10]

These changes are discussed in more detail in the sections that follow.

BASIC LIFE SUPPORT (BLS)

The general flow of basic life support management is outlined in the 2010 Basic Life Support flow chart of ANZCOR (**Fig. 21.1**).[8]

COMMENCEMENT OF CARDIOPULMONARY RESUSCITATION

The current BLS guidelines recommend that CPR be commenced if the victim is unresponsive and not breathing normally.[8,9] An appropriately trained ALS provider can check for a central pulse (e.g. carotid) for up to 10 seconds during this period of assessment, but this should not delay CPR. It is now recommended that CPR should start with compressions.[8,9]

EXTERNAL CARDIAC COMPRESSION

SITE OF COMPRESSION

The desired compression point for CPR in adults remains over the lower half of the sternum. Compressions that are provided higher than this become less effective, and compressions lower than this are also less effective and have an increased risk of damage to intra-abdominal organs.

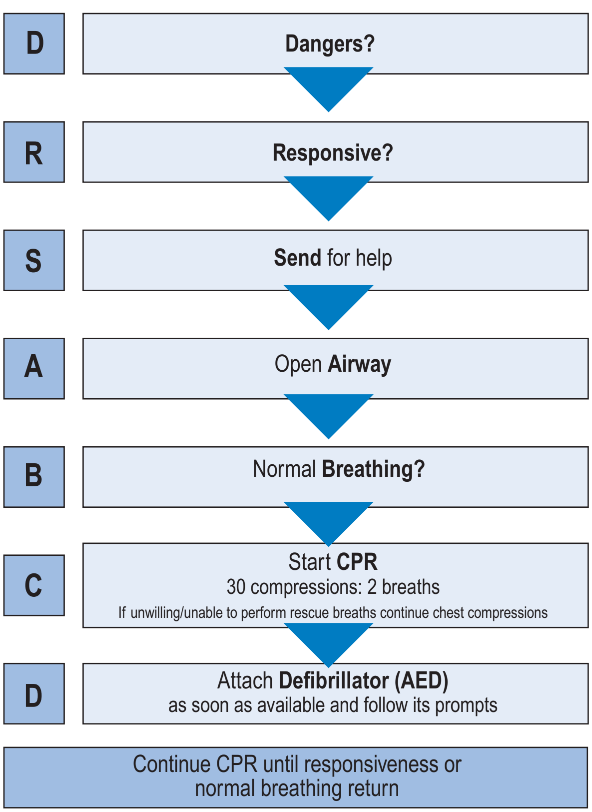

Figure 21.1 Basic life support flow chart. *Reproduced with permission from the Australian Resuscitation Council (www.resus.org.au).*[8]

RATE OF COMPRESSION

The optimal rate of cardiac compression during cardiac arrest in adults has not yet been determined.[2] In a recent human study,[11] lower rates (e.g. <80/min) were associated with worse outcomes and higher rates (>120/min) with more fatigue, and shallower compressions.[12] It is recommended that chest compressions should be performed at a rate of approximately 100 compressions/min.[8]

DEPTH OF COMPRESSION

The recommended compression depth for adults is now at least 5 cm.[8,9] It is still recommended that when performing chest compressions in adults (or infants or children) the chest should be compressed approximately one-third of its depth. In adults this facilitates delivery of at least 5 cm of compression.[8,13]

MINIMISE INTERRUPTIONS TO COMPRESSIONS

Interruptions in chest compressions ('hands-off time') are common, often prolonged, and are associated with a decrease in coronary perfusion pressure and a deceased likelihood of defibrillation success.[14] These adverse effects commence within 10 seconds of stopping CPR, but appear to be at least partially reversible with the recommencement of chest compressions. It is recommended that chest compressions be commenced as soon as the victim is confirmed to be unresponsive and not breathing normally.[8,9] The frequency and duration of interruptions in compressions for rhythm recognition or specific interventions (such as ventilations, charging the defibrillator, defibrillation, or intubation) should be kept to a minimum.

COMPRESSION : VENTILATION RATIO

The minute ventilation requirements during cardiac arrest are less than that in the non-arrested state as the cardiac output is reduced to approximately one-third of normal. A single compression : ventilation ratio of 30 : 2 remains recommended for adult BLS before the airway is secured (irrespective of the number of rescuers). This approach increases the number of compressions given per minute, minimises interruptions to chest compressions, and simplifies instruction for teaching and skills retention. The tidal breath should be delivered within 1 second, and the desired tidal volume to be delivered is one that results in a visible chest rise.[8]

MONITORING THE QUALITY OF CPR

A number of different techniques are available to monitor the quality of CPR, some of which are more

Box 21.1 Utility of end-tidal carbon dioxide monitoring during cardiac arrest[29]

Cardiovascular (absolute value of $ETCO_2$)
Falls immediately at the onset of cardiac arrest
Increases immediately with chest compressions
Provides a linear correlation with cardiac index
Allows early detection of ROSC (sudden increase)

Respiratory ($ETCO_2$ waveform)
Allows assessment of endotracheal tube placement
Allows assessment of expiratory flow limitation

Prognosis (absolute value of $ETCO_2$)
Predicts successful resuscitation

applicable to advanced life support.[10] Simple monitoring techniques include observing of the rate, depth and positioning of chest compressions, the rate and depth of ventilation, and palpating central pulses. Waveform capnography should be considered for all arrests (**Box 21.1**).[8] Additional monitoring techniques that can be used include: mechanical devices (e.g. for monitoring the depth of compressions) and new monitor/defibrillators (e.g. for monitoring the depth and rate of compressions and ventilation). Feedback from these devices has improved the quality of CPR but have not yet been translated into improvement in other outcomes.[15]

Feedback after cardiac arrests, as part of quality improvement, has been associated with improved cardiac arrest performance.[16]

'COMPRESSION-ONLY' CPR

Increasing anxiety about the performance of mouth-to-mouth ventilation has required the consideration of an alternative approach to traditional bystander CPR. A number of animal and human studies have suggested that ventilation may not be necessary during the initial phase of resuscitation from an arrest of a cardiac cause. Recent studies have shown benefits with conventional CPR in a number of settings (e.g. witnessed arrests,[17] and arrests with a non-cardiac aetiology[18]).

Despite the limited data to support 'compression-only' CPR, it is recommended that if rescuers are unable, not trained, or unwilling to perform mouth-to-mouth ventilation (rescue breathing) then they should perform 'compression only' CPR, as 'any attempt at resuscitation is better than no attempt'.[8]

DEFIBRILLATION

Defibrillation remains the definitive treatment for shockable rhythms such as pulseless ventricular tachycardia or ventricular fibrillation. Successful defibrillation requires an appropriate combination of defibrillator waveform and energy level.[8]

EARLY DEFIBRILLATION VS CPR BEFORE DEFIBRILLATION

The timing of defibrillation with regard to other interventions appears crucial. The traditional approach to the treatment of a shockable rhythm during cardiac arrest has been to perform defibrillation as soon as possible. In the scenario of recent-onset VF, this still holds, and the best outcomes are associated with defibrillation within 3 minutes (e.g. in electrophysiology labs or coronary care units). However, in situations where the VF has persisted for more than a few minutes, an initial period of CPR could be considered before defibrillation.[19]

WAVEFORM FOR DEFIBRILLATION

No specific defibrillator waveform (either monophasic or biphasic) is consistently associated with a greater incidence of return of spontaneous circulation (ROSC) or increased hospital discharge rates from cardiac arrest due to ventricular fibrillation. Defibrillation with biphasic waveforms (either truncated exponential or rectilinear), using equal or lower energy levels, appears at least as effective as monophasic waveforms for termination of VF.[20]

ENERGY LEVELS

Recommendations for energy levels to be used for defibrillation vary according to the type of defibrillator (and the specific waveform) that the rescuers are using. Current recommendations are based on maximising the likelihood of the success of each shock. The recommended energy level for defibrillation in adults where monophasic defibrillators are used is 360 J for all shocks. When using biphasic waveforms, the energy level should be set at 200 J for all shocks unless there exist relevant clinical data for the specific defibrillator suggesting that an alternative energy level provides adequate shock success (e.g. >90%). There is no consistent evidence (e.g. survival benefit) to suggest that an escalation of energy levels is required for subsequent shocks.[21]

MANUAL DEFIBRILLATION OR AUTOMATED EXTERNAL DEFIBRILLATOR

Automated external defibrillators provide an opportunity for untrained bystanders and BLS providers to defibrillate a shockable rhythm. In the hands of skilled healthcare providors, manual defibrillation should be used whenever possible as the delays inherent in the use of an AED may be detrimental.[22]

SINGLE-SHOCK TECHNIQUE

The use of a single-shock strategy for defibrillation is recommended (i.e. deliver a single shock and then

immediately commence CPR). This strategy minimises the interruptions to chest compressions that occur during defibrillation attempts.

The Australian Resuscitation Council does, however, recommend the consideration of a stacked shock strategy (up to three shocks as necessary) in specific circumstances: patients with a perfusing rhythm who develop a shockable rhythm, in a witnessed and monitored setting, where a manual defibrillator is immediately available (e.g. first shock able to be delivered within 20 seconds) and the time required for rhythm recognition and charging of the defibrillator is short (e.g. <10 seconds). All subsequent shocks should be given using a single-shock strategy.[8]

PADS OR PADDLES

Self-adhesive defibrillation pads are safe and effective for defibrillation, can facilitate pacing and allow charging during compressions.[20] If there are concerns about contact or success of defibrillation, then paddles can be used, but they require the use of conductive gel pads and the application of sufficient firm pressure to maximise electrical contact.[8]

ADVANCED LIFE SUPPORT

Advanced life support has an established role in the management of cardiac arrests. Interestingly, in of itself, the provision of ALS (apart from defibrillation) has not been specifically demonstrated to be associated with improved outcomes. A number of ALS techniques are listed below; some of these are available only in the in-hospital setting.

ADVANCED LIFE SUPPORT FLOW CHART

The recommended sequence of treatment to be followed is outlined in the 2010 Advanced Life Support flow chart of ANZCOR[8] (**Fig. 21.2**). This flow chart is based on ILCOR's universal algorithm[6] and is designed for use as an aide memoire and a teaching tool.

PRECORDIAL THUMP

The provision of a precordial thump may be considered in a monitored arrest due to pulseless ventricular tachycardia if a defibrillator is not immediately available. The technique is not without risks, however, and should not delay defibrillation.

A precordial thump is no longer recommended for ventricular fibrillation.[8]

CHEST COMPRESSIONS

The provision of good basic life support is an essential part of the advanced life support management of both shockable and non-shockable rhythms. Interruptions to chest compressions for definitive procedures or interventions should be kept as brief as possible.[9,23] Chest compressions should be continued up until defibrillation, including during charging of the defibrillator.[10,24] CPR should also be commenced again immediately following defibrillation (without checking the rhythm), and continued for at least 2 minutes unless signs of life return (the victim becomes responsive or starts breathing). Even if defibrillation has successfully reverted the rhythm into one that could generate a pulse, in the vast majority of cases this is not initially associated with an output. Immediate compressions in these situations avoid the detrimental effects of prolonged interruptions in compressions and maintain the coronary perfusion.[20] After each 2 minutes of CPR (or if signs of life return), the underlying rhythm should be checked, and if a rhythm compatible with a return of spontaneous circulation is observed at that time then a central pulse should also be checked.

AIRWAY MANAGEMENT DURING CPR

There are no data to support the routine use of any specific approach to airway management during cardiac arrest.[10] Despite this, endotracheal intubation remains the gold standard for airway maintenance and airway protection during CPR.[8] If the victim is unconscious and has no gag reflex, and a trained operator is available, endotracheal intubation should be performed at the first appropriate opportunity.[25] The endotracheal tube provides optimal isolation and patency of the airway, allows suctioning of the airway and also provides access for the delivery of some drugs (e.g. epinephrine (adrenaline), lidocaine and atropine). However, attempts at endotracheal intubation should not interrupt cardiac compressions for more than 20 seconds. The routine use of an endotracheal tube during cardiac arrest management has not been shown to improve outcomes, and without adequate training and experience the incidence of complications, such as unrecognised oesophageal intubation, is unacceptably high. A large number of supraglottic airway devices have been trialled as alternatives to the endotracheal tube.[26] The training and experience of the resuscitation team members, and availability of such devices, will determine the appropriate choice of airway adjunct.

VENTILATION DURING CPR

A compression : ventilation ratio of 30 : 2 is recommended before the airway is secured, and after the airway is secured the recommended ventilation rate is 8–10/minute.[10] One way to provide this, and to minimise interruptions to compressions is to use a compression : ventilation ratio of 15 : 1 once the airway is secured.[8] Hyperventilation during cardiac arrest is associated with increased intrathoracic pressure, decreased coronary and cerebral perfusion, and, at least

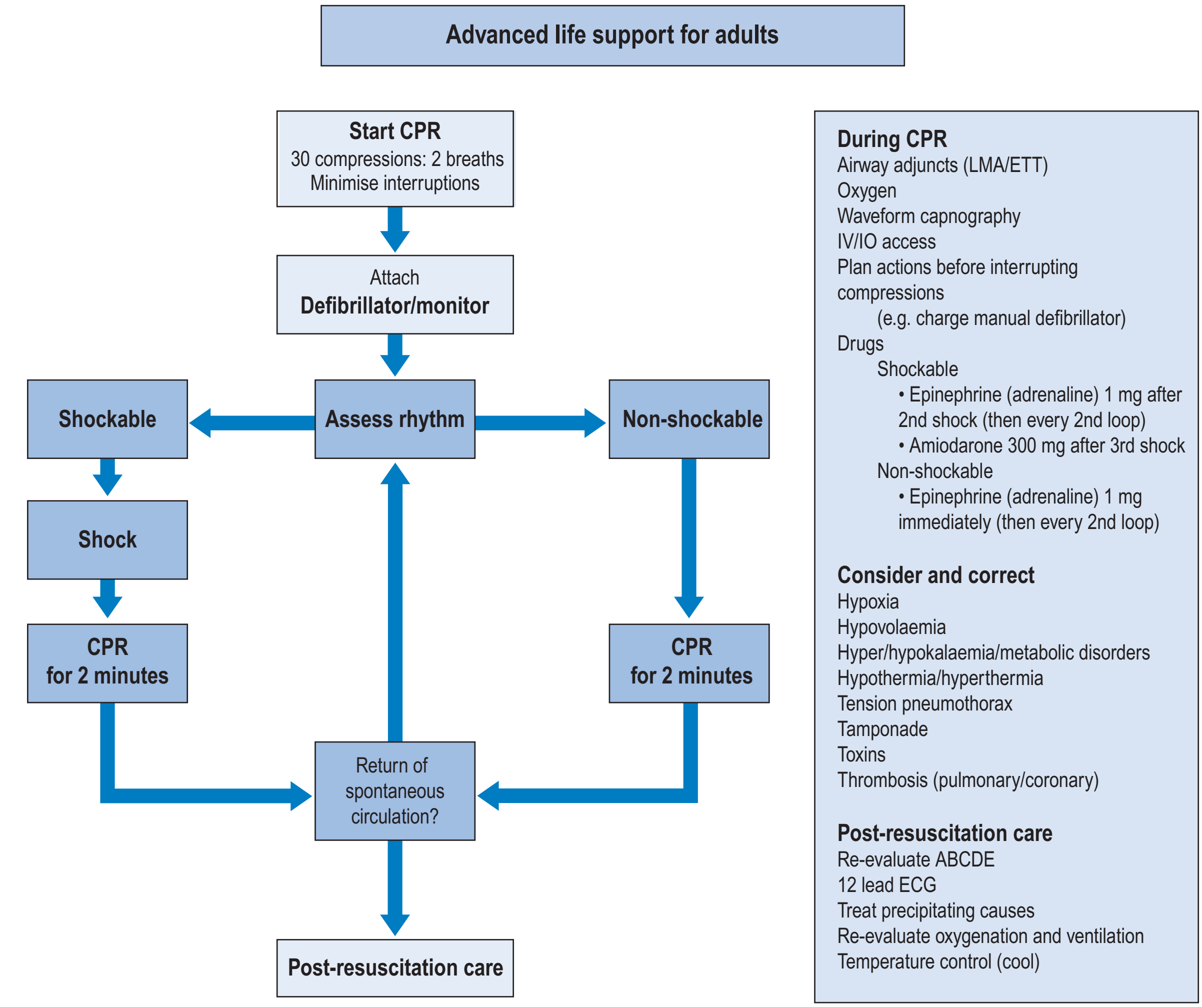

Figure 21.2 Advanced life support flow chart. *Reproduced with permission from the Australian Resuscitation Council (www.resus.org.au).*[8]

in animals, a decreased rate of return of spontaneous circulation.[27] If there is a concern about potential gas trapping, a period of disconnection from the ventilation circuit may be beneficial.[8] The tidal volume recommended is one that results in a visible chest rise.[8]

IDENTIFICATION OF REVERSIBLE CAUSES

Irrespective of the initial or subsequent rhythms, cardiac arrests can be precipitated or perpetuated by a number of conditions that if not detected and corrected may decrease the likelihood of successful resuscitation.[5] These 'reversible causes' are categorised in the ALS algorithm as the '4Hs and 4Ts' (www.resus.org.au; see 4Ts'[8] (Fig. 21.2, 'Consider and correct')). A number of techniques are available to assist in the diagnosis and exclusion of these conditions. These include a good history, a careful clinical examination, and some specific investigations and interventions. Echocardiography can potentially diagnose (or help exclude) a number of cardiac and non-cardiac reversible causes[28] (**Box 21.2**). Transoesophageal echocardiography requires a more skilled technician, but useful information can be obtained after minimal training with the transthoracic approach.[29]

MEDICATIONS DURING CPR

Although various drugs are recommended for use during the management of cardiac arrests, there are no placebo-controlled studies that show that the routine use of any drugs at any stage during human cardiac arrest increase survival to hospital discharge.[8] The intraosseous route should be considered for administration of medications if venous access is not immediately available.[30]

Box 21.2 Potentially useful diagnoses detectable by echocardiography[29]

Hypovolaemia*

Ventricular rupture
Aortic dissection
Massive pleural effusion

*Reversible causes listed in the '4Hs and 4Ts' (www.resus.org.au) (Fig. 21.2).

VASOPRESSORS

The putative beneficial effect of vasopressors during cardiac arrest is to increase the perfusion pressure to the heart and brain. The use of intravenous epinephrine (adrenaline) in randomised controlled trials enrolling out-of-hospital cardiac arrests has been associated with improved short-term survival, but no definitive increase in survival to hospital discharge.[31,32] Given these data, it is considered reasonable to continue to use a vasopressor routinely in the management of cardiac arrests. There are insufficient data to support any particular drug or combination of drugs. Epinephrine remains the vasopressor of choice during the management of cardiac arrest. The initial adult dose is 1 mg and this should be repeated approximately every 4 minutes. Vasopressin is an alternative drug, but studies have been unable to demonstrate that it has any consistent benefits.[33]

ANTI-ARRHYTHMICS

No anti-arrhythmic drug has been shown to improve long-term survival compared with placebo for the management of cardiac arrests.[8] However, administration of amiodarone (300 mg or 5 mg/kg) for shock refractory ventricular fibrillation has been associated with an increased survival to hospital when compared with either placebo or lidocaine. Either amiodarone or lidocaine (but not both) should be considered in those patients still in ventricular fibrillation after repeated attempts at defibrillation (including attempted defibrillation after the administration of epinephrine) have failed (i.e. immediately after the third shock).[8]

OTHER MEDICATIONS

Other medications that should be considered during cardiac arrest are those that address the underlying cause. These include electrolytes (such as magnesium or potassium), atropine, sodium bicarbonate and other specific 'antidotes' (see **Table 21.1**).[34,35]

Table 21.1 Cardiac arrest medications in specific circumstances

MEDICATION	POTENTIAL INDICATIONS
Atropine	Cholinergic/cardiac glycoside toxicity
Anti-venom	Snake, funnel-web spider, box jellyfish venom
Benzodiazepines	Sympathomimetic toxicity
Calcium	Hypocalcaemia, hypermagnesaemia, hyperkalaemia, beta-blocker/calcium channel blocker toxicity
Digoxin-specific antibodies	Cardiac glycoside toxicity
Flumazenil	Benzodiazepine toxicity
Epinephrine (adrenaline)	Beta-blocker/calcium channel blocker toxicity
Glucagon	Beta-blocker/calcium channel blocker toxicity
High-dose insulin/dextrose	Beta-blocker/calcium channel blocker toxicity
Lipid emulsion	Local anaesthetic agents
Magnesium	Hypomagnesaemia, hypokalaemia, hypercalcaemia, tricyclic antidepressant/cardiac glycoside toxicity, torsade de pointes
Naloxone	Opioid toxicity
Potassium	Hypokalaemia
Pyridoxine	Isoniazid toxicity
Sodium bicarbonate	Hyperkalaemia, tricyclic antidepressant/sodium-channel-blocker toxicity

ADJUNCTS TO CPR

Many technologies and techniques have been evaluated as adjuncts to CPR in an attempt to improve survival in the management of cardiac arrests, but none has been consistently associated with improved outcomes.[36] Active-compression decompression (ACD) CPR is the most widely evaluated technique, but by itself has not been associated with improved long-term survival. The combination of ACD-CPR with an impedance threshold device was associated with improved neurological survival in one recently published trial in out-of-hospital cardiac arrests.[37] An automated version of ACD-CPR (LUCAS), and a modification of vest CPR (the load-distributing band) are both currently being evaluated in controlled trials. There has also been a resurgence of interest in extracorporeal techniques, especially as short-term rescue.[38] At this stage there is still insufficient supportive evidence to recommend the routine use of any of these adjunctive techniques.[8,10]

Mechanical devices (such as LUCAS or the load-distributing band) may, however, be useful alternatives to manual CPR in situations where tradional CPR is difficult or hazardous (e.g. during transport, or during interventions).[10,39]

POST-RESUSCITATION CARE

The missing link in research in resuscitation has for a long time been the period of care after the return of spontaneous circulation. Survival after cardiac arrest is largely dependent on the patient's co-morbidities and the initial hypoxic insults to the heart and brain. However, survival is also influenced by subsequent complications (including secondary insults and the ensuing systemic inflammatory response[40]), and possibly differences in post-resuscitation care[41] (**Box 21.3**).

RESUSCITATION CENTRES

An increasing body of evidence suggests that there may be benefits in transporting the victims of out-of-hospital cardiac arrests to a centre that is equipped to provide all of the desired components of post-arrest care (including percutaneous coronary interventions and therapeutic hypothermia).[42,43]

Box 21.3 Key factors to consider after resuscitation from cardiac arrest[8]

Immediate tasks
Re-evaluate ABCDE
12-lead ECG
Treat precipitating causes
Re-evaluate oxygenation and ventilation
Temperature control (cool)

Early goals
Continue respiratory support
Maintain cerebral perfusion
Treat and prevent cardiac arrhythmias
Determine and treat the cause of the arrest

Specific tasks
Maintain haemodynamics (SBP>100 mmHg (13 kPa))
Maintain adequate oxygenation (Sa_{O_2} 94–98%)
Maintain normal pH and normocarbia (e.g. Pa_{CO_2} 35–40 mmHg (4.5–5.2 kPa))
Treat hyperglycaemia (>10 mmol/L), but avoid hypoglycaemia
Consider therapeutic hypothermia (unless contraindicated)
Maintain appropriate sedation
Treat seizures
Continue search to identify underlying cause(s) and trauma related to resuscitation
Consider specific treatment for underlying cause (e.g. percutaneous coronary intervention, thrombolytics)
Consider prophylactic antiarrhythmics
Consider transfer to resuscitation centre

THERAPEUTIC HYPOTHERMIA

It is recommended that unconscious but haemodynamically stable survivors of out-of-hospital cardiac arrests due to ventricular fibrillation should be cooled to 32–34°C for 12–24 hours. A period of induced hypothermia should also be considered for cardiac arrests due to other rhythms, as well as in-hospital arrests.[8,10,44] (See Ch. 50 for further details.)

OTHER FACTORS IN POST-RESUSCITATION CARE

Factors other than therapeutic hypothermia are important in the post-arrest period. Attention should be given to good supportive care, including maintenance of cerebral perfusion, provision of adequate oxygenation, ventilation to normocarbia, avoidance of hyperglycaemia and treatment of seizures. Norwegian investigators were able to double their survival to hospital discharge (with a favourable neurological outcome) for out-of-hospital cardiac arrests by introducing a standardised post-resuscitation protocol. This protocol focused on vital organ function including the use of therapeutic hypothermia, percutaneous coronary interventions (PCI), and the control of haemodynamics (MAP>65 mmHg (8.5 kPa)), blood glucose (5–8 mmol/L), ventilation (normocapnia) and seizures.[45]

OXYGENATION

Traditional approaches to resuscitation have included the routine use of 100% oxygen. Data from animal and neonatal studies have suggested that this may be associated with adverse outcomes.[8] The adult cardiac arrest evidence regarding effects of oxygenation is accumulating, but is of low quality and remains controversial.[46,47] It seems reasonable, however, to titrate the Fi_{O_2} to target an acceptable Sa_{O_2} (e.g. 94–98%) as soon as the patient is stable.[8]

VENTILATION

Numerous studies in animals and humans have demonstrated the potential harm of cerebral ischaemia induced by hypocapnia after cardiac arrest. There are no data to support the targeting of a specific Pa_{CO_2} after resuscitation from cardiac arrest, but data extrapolated from patients with brain injury however, imply that ventilation to normocarbia (e.g. Pa_{CO_2} 35–40 mmHg (4.5–5.2 kPa)) is appropriate.[8] Arterial blood gas measurements should be used to titrate ventilation in the immediate post-resuscitation period, rather than the use of end-tidal CO_2 levels as there may be disparity.[8]

BLOOD PRESSURE CONTROL

There is limited human evidence to support specific haemodynamic goals after cardiac arrest. Reported successful blood pressure goals have varied from a period of relative hypertension (MAP 90–100 mmHg[48]

(11.7–13 kPa)), to more standard goals (MAP>65–70[45]). It is recommended to aim for a blood pressure equal to the patient's usual blood pressure or a systolic pressure greater than 100 mmHg.[8]

GLUCOSE CONTROL

Despite the early promise of improved outcomes with tight blood glucose control, subsequent studies have demonstrated this approach to be potentially harmful.[49] Blood glucose should be monitored frequently after cardiac arrest. Hyperglycemia (>10 mmol/L) should be treated with insulin, but hypoglycemia should be avoided.[8]

PERCUTANEOUS CORONARY INTERVENTION

Thrombolysis and percutaneous coronary interventions (PCI) are the mainstay of management after acute coronary syndromes. PCI has been used successfully when indicated in the early period after recovery of spontaneous circulation, and should be considered as part of routine post-arrest care in patients with ST elevation or a new left-bundle branch block.[50] Clinical findings of coma in patients prior to PCI are commonly present in out-of-hospital cardiac arrest (OHCA) patients, and these should not be a contraindication to consider immediate angiography and PCI. It is also reasonable to perform immediate angiography and PCI in selected patients, despite the absence of ST-segment elevation on the ECG or prior clinical findings such as chest pain.[51]

Therapeutic hypothermia is recommended in combination with primary PCI, and should be started as early as possible, preferably prior to initiation of PCI.

TREATMENT OF SEIZURES

Seizures are relatively common after cardiac arrest (3–44% incidence),[10] and in the post-arrest period they may be refractory to multiple medications. It is reasonable to intstitute prompt and aggressive treatment of seizures, but there is no definitive evidence to suggest that this approach (or preventative therapy) improves outcomes.[10]

OTHER FACTORS

The search should be continued to identify and treat underlying causes of the arrest. Trauma related to the resuscitation is relatively common, and should be identified and treated as appropriate.[8]

It may be reasonable to continue an infusion of an antiarrhythmic drug that successfully restored a stable rhythm during resuscitation (e.g. lidocaine 2–4 mg/min or amiodarone 0.6 mg/kg/h for 12–24 hours). If no antiarrhythmic drug was used during resuscitation from a shockable rhythm, an antiarrhythmic drug may be considered to prevent recurrent VF.

The placement and sterility of devices inserted during the arrest should also be reviewed.[8]

PROGNOSTICATION

It is impossible to predict accurately the degree of neurological recovery during or immediately after a cardiac arrest.

In adult patients who are comatose after cardiac arrest, who have not been treated with hypothermia and who do not have confounding factors (such as hypotension, sedatives or neuromuscular blockers), the absence of both pupillary light and corneal reflexes at 72 hours after arrest reliably predicts a poor outcome.[10] The absence of vestibulo-ocular reflexes at 24 hours and a GCS motor score of 2 or less at 72 hours are less reliable. Other clinical signs, including myoclonus, are not recommended to be used for predicting poor outcome.[52] After 24 hours, bilateral absence of the N20 cortical response to median nerve stimulation predicts poor outcome in comatose cardiac arrest survivors not treated with therapeutic hypothermia.

Accurate prediction of neurological outcome has become increasingly difficult since therapeutic hypothermia has been used in the post-arrest period.[10,53] A Glasgow Motor Score of 2 or less at 3 days after sustained return of spontaneous circulation and the presence of status epilepticus are potentially unreliable prognosticators of poor outcome in POST-cardiac arrest patients treated with therapeutic hypothermia. Given the limited available evidence, decisions to limit care should not be made based on the results of a single prognostication tool.[8,53]

The use of EEG, neuroimaging and biochemical markers may provide additional information, but at this stage are not sufficiently reliable to be used definitively for prognostication.[54]

MAINTENANCE OF ALS SKILLS

Many studies have confirmed that knowledge and skills related to ALS start to deteriorate relatively quickly (e.g. within 6 months).[55] New approaches to ALS teaching are required to ensure all staff maintain their skills. One successful approach has been to provide 6 minutes of practice every month.[56]

SUMMARY

Improved outcomes after cardiac arrest have been demonstrated in many centres over the past decade. This is almost certainly due to improvements made within each link of the chain of survival. These include: earlier recognition and activation of the emergency response (both pre-hospital and in-hospital), provision of good-quality basic life support (including minimising interruptions to chest compressions), optimised defibrillation, early and appropriate advanced life support with attention to identifying and treating underlying causes, and an increased focus on care in the critical post-resuscitation period.

Management of cardiac arrhythmias

Andrew Holt

CARDIAC ELECTROPHYSIOLOGY

The electrophysiological properties of cardiac cells are important in understanding cardiac arrhythmias and their management. Cardiac cells undergo cyclical depolarisation and repolarisation to form an action potential. The shape and duration of each action potential are determined by the activity of ion channel protein complexes on the myocyte surface (**Table 22.1**).[1]

Ion channels are large glycoproteins that span the membrane bilayer with accessory subunits that contribute to pore structure or modulate function. Channel activation forms pores that permit rapid transit of ions creating ionic currents that determines the magnitude and rate of change of myocyte membrane potential.

Ion channels:

- are generally highly selective for certain ions
- activation control or 'gating' can be voltage or ligand binding
- most are voltage gated and modulated by ligand gating
- have 'rectifying' properties whereby they conduct ions more effectively in one direction.

Many of the ion channels are the molecular targets for antiarrhythmic drugs. The differential distribution of ion channel populations within the heart allows drugs to have preferential activity on different parts of the heart.

I_f 'pacemaker' channels are confined to the SA node and new drugs with specific I_f blocking activity such as ivabradine have been shown to be beneficial in angina and heart failure by slowing the heart rate without negative effects on ventricular contractility.

I_K channels responsible for potassium ion (K^+) repolarisation currents (I_K) vary throughout the heart with the rapidly activating forms, I_{Kur}, being confined to the atrium. Vernakalant, a new K channel blocker has predominant activity on the I_{Kur} channel and therefore predominant atrial activity.

Ion channel function can be affected by:

- genetic mutations of channel proteins
- changes in functional expression of channel protein genes
- acute ischaemia
- autonomic tone
- myocardial scarring
- electrolyte concentration.

The spectrum of cardiac action potentials varies from *fast-response* cells – conducting and contractile myocytes (**Fig. 22.1a**) – to *slow-response* cells of pacemaker myocytes – sinoatrial (SA) and atrioventricular (AV) nodes (Fig. 22.1b). Fast myocytes lose their characteristic action potential and behave more like slow myocytes when ischaemic. The action potential is divided into five phases and ion channel currents vary between fast- and slow-response cells (**Fig. 22.2**).

PHASE 0

In fast myocytes (see Fig. 22.1a) rapid depolarisation I_{Na} current occurs owing to activation of voltage-gated sodium ion (Na^+) channels. Activation is initiated in an all-or-none response once the threshold is reached. The Na^+ channels are inactivated as membrane potential rises to +30 mV and remain inactivated until repolarisation occurs. Rapidity of depolarisation determines speed of conduction. In slow-response myocytes depolarisation does not involve Na^+ channels and the slower rate of depolarisation is due to a slow inward calcium ion (Ca^{2+}) current via $I_{Ca\text{-}L}$ and $I_{Ca\text{-}T}$ voltage-dependent Ca^{2+} channels.

PHASE 1

Early rapid incomplete repolarisation to approximately 0 mV occurs owing to activation of transient outward current from I_{TO1} and I_{TO2} K^+ channels. Slow myocytes do not exhibit phase 1 or 2 characteristics (see Fig. 22.1b).

PHASE 2

The prolonged plateau repolarisation of fast myocytes is a consequence of low membrane conductance to all ions. The decreasing inward Ca^{2+} current of $I_{Ca\text{-}L}$ and $I_{Ca\text{-}T}$ Ca^{2+} channels is initially balanced and then overcome by the outward K^+ current of the delayed rectifiers or the I_k family of K^+ channels. During this phase the rise in calcium ion concentration ($[Ca^{2+}]_i$) is the trigger to release sarcoplasmic reticulum stores of Ca^{2+} and initiate the contractile process.

Table 22.1 Characteristics of cardiac ionic channels

ION	CHANNEL	
		INWARD CURRENT/DEPOLARISATION
Sodium Na_v	I_{Na}	• Present in atria, His–Purkinje and ventricle • Absent in sinoatrial and AV node • Generates phase 0 rapid depolarisation current • Drives action potential propagation
Calcium Ca_v	$I_{Ca\text{-}L}$	• Predominate Ca^{2+} channel • Contributes to phase 2 plateau • Produces depolarisation and propagation in SA and AV nodes • Triggers Ca^{2+} release from sarcoplasmic reticulum
	$I_{Ca\text{-}T}$	• Predominates in pacemaker cells • Contributes to later stages of phase 4 in pacemaker cells
Non-selective cation	I_f	• Predominately Na • Absent in ventricular cells • Activated by polarisation • Generates phase 4 depolarisation of pacemaker function • Strongly modulated by neurotransmitters
		OUTWARD CURRENT/REPOLARISATION
Potassium K_v	I_{to}	• Activated rapidly after depolarisation • Fast I_{to1} and slow I_{to2} variants • Responsible for phase 1 rapid early repolarisation • Predominate distribution subepicardial • Distribution creates heterogeneous repolarisation
	I_K	• Delayed rectifiers • Slow activation kinetics • Major repolarising current • Variants with slow I_{Ks}, rapid I_{Kr} and ultra-rapid I_{Kur} activation • I_K populations are not characterised in the SA node • I_{Kur} are not present in the ventricle • I_{Kur} along with I_{to} contributes to earlier repolarisation and shorter action potentials of atrial cells
	I_{K1}	• Inward rectifier • Current responsible for maintaining resting potential near K^+ equilibrium • Shuts off during depolarisation • Absence in SA node enables small currents to control pacemaker rates

PHASE 3

Relatively rapid repolarisation occurs as outward K^+ current of the delayed rectifiers increases. The I_{kr} K^+ channel, one of the I_k delayed rectifiers, is the common mechanism whereby antiarrhythmic drugs prolong the action potential and refractoriness.

PHASE 4

This is a stable electrical state in fast non-pacemaker myocytes owing to inward rectifier I_{K1} channels maintaining resting membrane potential near K^+ equilibrium and the absence of I_f pacemaker channels. In slow pacemaker myocytes the resting membrane potential (RMP) slowly depolarises owing to absence of I_{K1} channels and progressive activation of I_f pacemaker channels until the action potential threshold is reached (see Fig. 22.1b).

Fast-response and slow-response myocytes also have important differences in properties of refractoriness. In fast myocytes, Na^+ channels are progressively reactivated during phase 3 repolarisation as the membrane potential becomes more negative. When an extra stimulus occurs during phase 3, the magnitude of the resulting inward Na^+ current and likelihood of impulse propagation depend on the number of reactivated Na^+ channels. Refractoriness is therefore determined by the voltage-dependent recovery of Na^+ channels. The absolute refractory period (see Fig. 22.1) is that minimum time needed for recovery of sufficient Na^+ channels for a stimulus to result in impulse propagation. However, once propagation in fast myocytes occurs, conduction velocity is normal. In contrast, slow-response or Ca^{2+} channel-dependent myocytes exhibit time-dependent refractoriness. Even after full repolarisation, further time is needed before all Ca^{2+} channels are reactivated. Stimuli during this period produce reduced Ca^{2+} current and the propagation velocity of any resulting impulse is reduced. The conduction velocity independence of

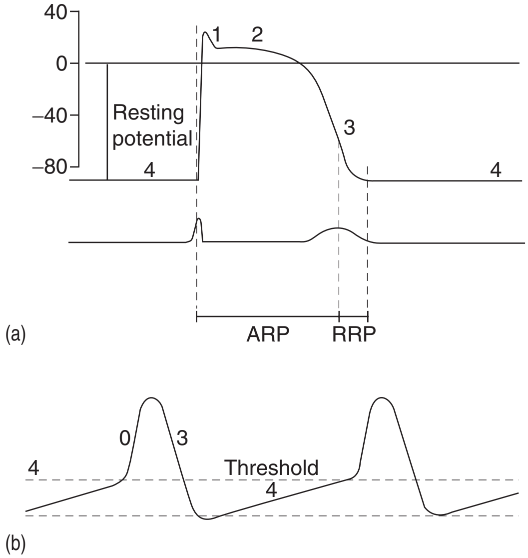

Figure 22.1 (a) Action potential in a fast-response, non-pacemaker myocyte: phases 0–4, resting membrane potential −80 mV, absolute refractory period (ARP) and relative refractory period (RRP). (b) Action potential in a slow-response, pacemaker myocyte. The spontaneous upward slope of phase 4, on reaching threshold potential, results in an action potential.

premature action potentials with fast-response myocytes is lost in the setting of Na^+ channel-blocking drugs or ischaemia because they behave increasingly like slow-response myocytes with resulting slowed impulse conduction.

RECEPTOR MODULATION OF CHANNEL FUNCTION

The autonomic nervous system is an important modulator of cardiac rhythm via effects on channel function. Beta-adrenergic receptor–effector-coupling system modulates channel function via cyclic adenosine monophosphate (AMP) phosphorylation of peptides associated with channels resulting in the following:

- I_{Ca-L} increases Ca^{2+} current and contractility
- I_f activation threshold is changed to a more positive level
- I_K accelerates K^+ current repolarisation and increases AV node conduction.

Muscurinic M_2 receptor activation inhibits cyclic AMP effects and purinergic A_1 receptor activation slows K^+ current and AV conduction.

GENETIC BASIS TO ARRHYTHMIA

In the absence of structural abnormalities of the heart, primary electrical disease is associated with mutations in ion channel genes. The long-QT syndrome (LQTS) (see below), short-QT syndrome, Brugada syndrome (idiopathic ventricular fibrillation, VF) and catecholaminergic polymorphic ventricular tachycardia (VT), and all causes of sudden cardiac death (SCD) in the young are examples of primary electrical disease where genetic mutations encoding for ion channel proteins have been characterised.

Inheritable forms of structural ventricular disease are associated with atrial arrhythmias and SCD. Examples include hypertrophic and dilated cardiomyopathies and arrhythmogenic right ventricular dysplasia, which are linked to mutations in sarcomeric, cytoskeletal and intercellular junction proteins, respectively.

The risk of cardiac arrhythmias and SCD in the setting of acquired structural heart disease such as ischaemic heart disease is in part genetically determined. Studies demonstrate an increased risk of SCD in patients who have a parental history of cardiac arrest.

MOLECULAR BASIS TO ARRHYTHMIA

Structural and electrical remodeling in response to myocardial injury, altered haemodynamic loads and changes in neurohumoral signalling lead to alterations in:

- ion channel function
- intracellular calcium handling
- intercellular communication
- composition of intercellular matrix.

All of these factors lead to heterogeneous slowing of conduction velocity and prolonged refractoriness.

Tachycardia remodelling of the atrium is associated with:

- reduced functional expression of L-type Ca^{2+} channels, intracellular Ca^{2+} overload and shortening action potential duration.

Heart failure is associated with:

- down-regulation of each of the major repolarising K^+ currents, prolonging repolarisation and resulting in susceptibility to early-after-depolarisation (EAD)-mediated arrhythmia. As these changes are heterogeneous they also create the substrate for re-entrant arrhythmias
- reduced Na^+ channel density decreasing conduction velocity
- increased expression of Na^+–Ca^{2+} exchanger protein, leading to intracellular Ca^{2+} overload and predisposition to delayed-after-depolarisation (DAD)-mediated arrhythmia.

Intercellular ion channels or connexins at gap junctions are decreased and redistributed from the intercalated disc to lateral cell borders, slowing conduction velocity and uncoupling myocytes.

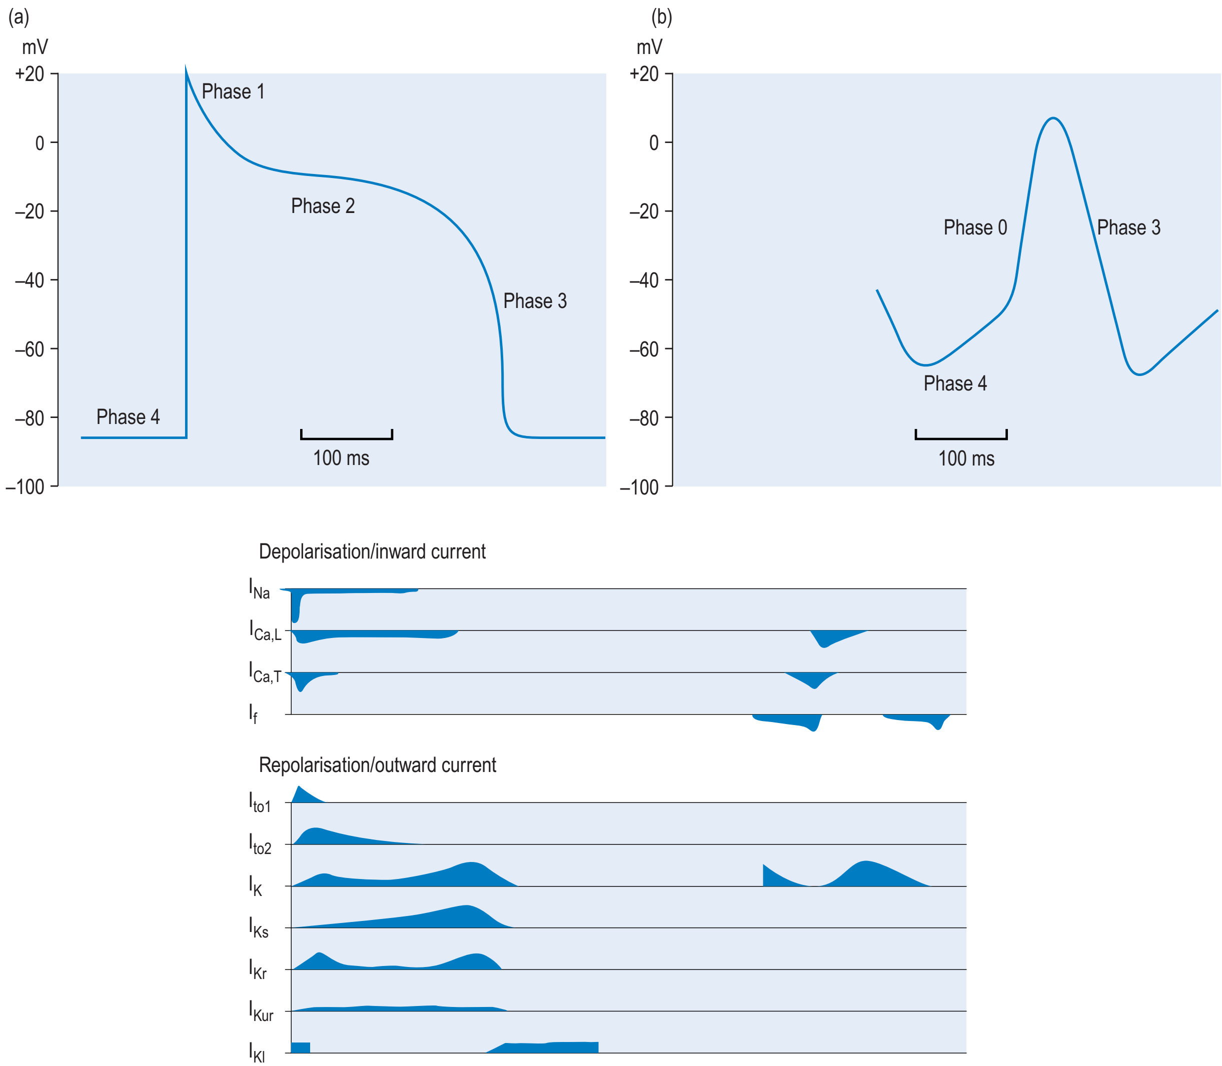

Figure 22.2 Temporal relationship between action potential and ionic channel activation for: (a) fast-response ventricular myocytes and (b) slow-response pacemaker myocytes.

Myocardial infarction scar produces:

- heterogeneous action potential duration with zones of healing myocytes with shortened action potential and surrounding hypertrophic myocytes with prolonged action potentials
- potential anatomical circuits due to fibrous tissue separating myocyte bundles.

ARRHYTHMOGENIC MECHANISMS

Many factors in isolation or combination give rise to the substrate of arrhythmogenesis (**Fig. 22.3**). Arrhythmia may arise from abnormalities of impulse generation or conduction. **Table 22.2** demonstrates the relationship between mechanism and type of arrhythmia, and desired antiarrhythmic effect.

ABNORMAL IMPULSE GENERATION (TABLE 22.3)

ENHANCED NORMAL AUTOMATICITY

Automaticity is the property of spontaneous impulse generation by cardiac myocytes. This results from spontaneous depolarisation during phase 4. In the SA node and subsidiary pacemaker myocytes phase 4 spontaneous depolarisation results from an inward current, predominantly Na^+ via the non-selective cation channel I_f. SA node discharge rate is influenced by changes to

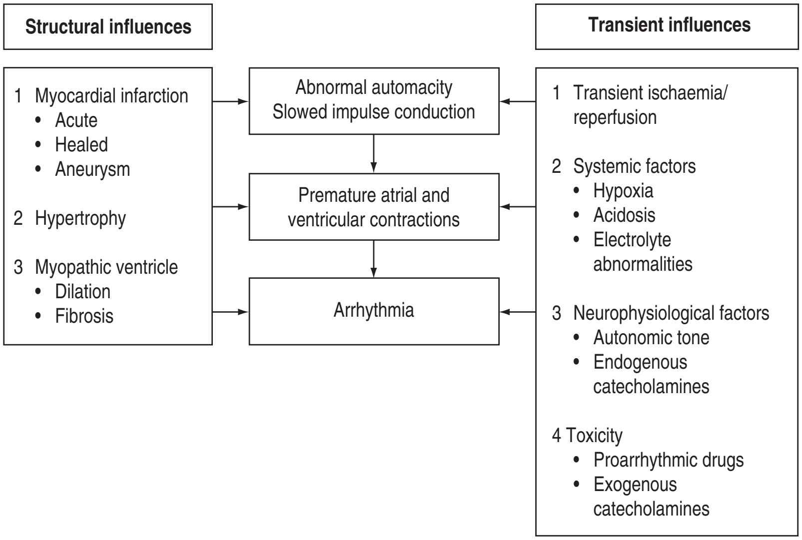

Figure 22.3 Factors that combine to form the substrate of arrhythmogenesis.

channel activity. Beta-adrenergic receptor stimulation increases both I_f and $I_{Ca\text{-}T}$ conductance and rate of phase 4 depolarisation by channel phosphorylation, whereas M_2 receptor increases I_k activity during phase 3 and early phase 4 to hyperpolarise myocytes, increasing time to reach depolarisation threshold.

Enhanced normal automaticity of subsidiary atrial pacemakers, for example around pulmonary veins, is an increasingly recognised cause of atrial fibrillation (AF).

ABNORMAL AUTOMATICITY

Abnormal automaticity is the mechanism by which spontaneous impulses are generated in myocytes that are partially depolarised by a pathological process. The less negative resting membrane potential (RMP) is associated with inactivation of the normal ionic currents of phase 4 depolarisation and the pacemaker current results from inward Na^+ and Ca^{2+} currents and is not readily susceptible to overdrive suppression from normal pacemaker activity. Due to this less negative membrane potential, these abnormal automatic myocytes inactivate the phase 0 fast inward Na^+ current, resulting in an impaired rate of impulse conduction (as well as contractility), which further contributes to arrhythmia. In this setting, Ca^{2+} carries the major inward current on depolarisation in these myocytes.

TRIGGERED ACTIVITY

Abnormal impulse generation from triggered activity originates from oscillations in the membrane potential that are initiated or triggered by a preceding action potential. There are two types of oscillations: EAD and DAD. EAD occurs during phase 2 or 3 of the action potential, whereas DAD occurs after the termination of depolarisation. The signal-averaged electrocardiograph (ECG) can detect after-depolarisations.

1. EADs appear as sub-threshold humps during the plateau or depolarisation phases. On reaching threshold, single or multiple action potentials can be induced. Plateau EADs are caused by an increased inward Ca^{2+} current (at this level of membrane potential, fast inward Na^+ channels are inactivated) and produce slow rising and propagating action potentials. Phase 3 EADs are caused by a reduction in outward K^+ currents and produce relatively rapidly rising and propagating action potentials. EAD amplitude and likelihood of triggered arrhythmia increase as driving rate decreases and action potential is prolonged. Tachyarrhythmia induced by EAD is more likely to occur on the background of a bradycardia.
2. DADs are produced by Na^+–Ca^{2+} exchanger current-induced oscillations in inward calcium current. These oscillations are caused by $[Ca^{2+}]_i$ overload saturating sarcoplasmic reticulum sequestration mechanisms, thereby leading to Ca^{2+}-induced Ca^{2+} release. Unlike EADs, DADs depend on previous rapid rhythm for their initiation.

ABNORMAL IMPULSE CONDUCTION[6]

Normal cardiac rhythm is dependent on orderly homogeneous conduction throughout atrial and ventricular tissue. This orderly homogeneity of impulse conduction can be lost by abnormal physical barriers to conduction such as infarction scars or functional disturbances in action potential leading to heterogeneity of impulse propagation. Magnitude and rate of depolarisation, presence of slow-response myocyte characteristics and rapidity of repolarisation influence speed of propagation. Functional disturbances in these properties are readily produced by channel receptor

Table 22.2 Classification of mechanisms of arrhythmia and desired antiarrhythmic drug action[3]

MECHANISM OF ARRHYTHMIA	ARRHYTHMIA	ANTIARRHYTHMIC EFFECT	REPRESENTATIVE DRUGS
AUTOMATICITY ENHANCED			
Normal	Inappropriate sinus tachycardia Unifocal atrial tachycardia	Decrease phase 4 depolarisation	Beta blocker Sodium channel blockers
Abnormal	Unifocal atrial tachycardia Accelerated idioventricular rhythms VT post myocardial infarction	Hyperpolarise or decrease phase 4 depolarisation	Calcium or sodium channel blockers M_2 agonists (muscarinic receptor)
TRIGGERED ACTIVITY			
Early after-depolarisation (EAD)	Torsade de pointes Digitalis-induced arrhythmias Some VT	Shorten action potential or suppress EAD	Increase heart rate with beta agonists or vagolytic agents, calcium channel blockers, beta blockers or magnesium
Delayed after-depolarisation (DAD)		Decrease calcium overload or suppress DAD	Calcium or sodium channel blockers, beta blockers, adenosine
RE-ENTRY: SODIUM CHANNEL DEPENDENT			
Long excitable gap	Afl type 1 Circus movement tachycardia in Wolff–Parkinson–White syndrome (WPW) Monomorphic VT	Depress conduction and excitability Prolong refractory period	Sodium channel blockers Potassium channel blockers
Short excitable gap	Afl type 2 Atrial fibrillation Circus movement tachycardia in WPW Polymorphic and monomorphic VT Bundle branch re-entry Ventricular fibrillation		
RE-ENTRY: CALCIUM CHANNEL DEPENDENT			
	Atrioventricular nodal re-entrant tachycardia Circus movement tachycardia in WPW VT	Depress conduction and excitability	Calcium channel blockers

Table 22.3 Causes of abnormal impulse generation

Enhanced normal automaticity	Adrenergic stimulation
Abnormal automaticity	Ischaemia
Early after-depolarisations	Hypoxia Hypercapnia Catecholamines Class IA antiarrhythmic drugs Class III antiarrhythmic drugs Other drugs that prolong repolarisation
Delayed after-depolarisations	Digoxin toxicity Increased intracellular Na^+ Decreased extracellular K^+ Increased intracellular Ca^{2+} Intracellular Ca^{2+} overload due to myocardial infarction or reperfusion after ischaemia

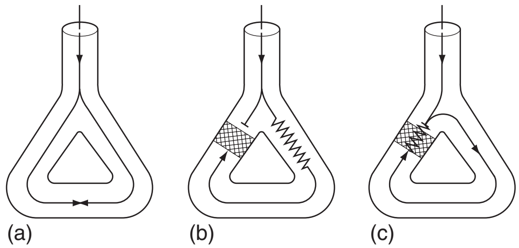

Figure 22.4 Re-entrant excitation. (a) Normal cardiac impulse conduction results in the impulse being extinguished. (b) Conduction down one limb is blocked by segment of refractory tissue (excitable gap). (c) The impulse is conducted back up the limb and arrives at the excitable gap, which has recovered from refractoriness and retrograde conduction is complete. If geometry and electrical properties are favourable, the excitable gap circulates around the re-entry loop and arrhythmia is initiated.

activation, ischaemia, hypertrophy and channel genetic mutation or expression.

Heterogeneity of impulse conduction may cause an arrhythmia by the phenomenon of re-entry. Re-entry describes the re-excitation of an area or entire heart by a circulating impulse. Although the classic 'bifurcating Purkinje fibre' model of Schmitt and Erlanger has given way to a much more complex picture, the essential electrophysiological requirements for re-entrant excitation remain. Requirements for re-entry are (**Fig. 22.4**):

- conduction block in one limb of the circuit
- slowed conduction in the other limb
- the impulse returns back along the limb initially blocked to re-enter and re-excite the pathway proximal to the block and complete the re-entry pathway.

When these properties are present, the chance of a circulating impulse producing re-entrant excitation depends on pathway geometry, the electrical properties and length of the depressed area and conduction velocity within each component. The segment of the re-entry pathway that is initially refractory and therefore blocks conduction down one limb and then recovers in time to conduct the return impulse is termed the 'excitable gap'. Therefore, the generation and subsequent maintenance of a circuit depend on this excitable gap of non-refractory tissue circulating between the advancing depolarising wave front and the repolarising tail. The resulting re-entrant impulse can be self-terminating; causing ectopic beats, or leads to atrial or ventricular tachyarrhythmia.

Risk of re-entry can be further modeled and quantified. Cardiac wavelength (λ) is the physical distance an electrical impulse travels in one refractory period; λ equals conduction velocity $\times$ refractory period (or action potential duration). Re-entry is critically dependent on the λ being shorter than the potential reentrant pathway. If λ exceeds the path length then the advancing impulse encroaches on the refractory tail and re-entry is terminated. Reducing λ (decreasing conduction velocity or refractory period) promotes re-entry circuits.

Re-entry may be terminated by:

- *increasing conduction velocity:* the excitable gap is abolished by the wave front arriving too early and meeting refractory tissue
- *increasing refractory period:* the excitable gap is lost
- *slowing conduction:* a unidirectional block can be converted into a complete block.

Ordered re-entry occurs along anatomical pathways which are 'macroscopic' loops (macro-re-entry), as in Wolff–Parkinson–White (WPW) syndrome. Functional circuits can be created following myocardial infarction, resulting in VT. 'Microscopic' loops (micro-re-entry) occur at the level of single fibres where antegrade and retrograde impulse propagation occurs in parallel fibres. Random re-entry refers to the generation of a circulating impulse, not from a fixed circuit but from constantly changing electrophysiologically distinct fibres or pathways created by the circulating impulse, resulting in AF or VF.

The cellular properties that lead to impaired conduction include:

- inactivation of the phase 0 fast Na^+ channels, which reduces both the magnitude and rate of propagation of any resultant action potential
- intercellular uncoupling, which increases resistance to action potential propagation and slows conduction. Intercellular coupling is reduced by ischaemia, $[Ca^{2+}]_i$ overload, acidosis and reduced expression of intercellular ion channel connexin proteins in diseases such as chronic heart failure.

ELECTROPHYSIOLOGICAL EFFECTS OF ISCHAEMIA

Both hypoxia and acidosis are implicated in the production of a less negative RMP in ischaemia. A rise in extracellular K^+ results from impairment of the adenosine triphosphate (ATP)-dependent K^+ inward channels. As $[K^+]_o/[K^+]_i$ is the major determinant of the RMP, intracellular K^+ loss results in a less negative RMP.

The consequences of this are:

- abnormal automaticity
- inactivation of the fast inward Na^+ channels, which slows the conduction velocity.

ELECTROLYTE ABNORMALITIES AND ARRHYTHMIA[7]

POTASSIUM

Hyper- and hypokalaemia both cause arrhythmia mediated by the resultant changes in RMP (**Table 22.4**).

Table 22.4 Arrhythmogenic effects of potassium disturbance

	ARRHYTHMOGENIC EFFECTS	ELECTROCARDIOGRAM CHANGES	ARRHYTHMIA
HYPERKALAEMIA	Less negative RMP Inactivation of fast Na^+ channels Slowed conduction velocity	Peaked T-waves Widening of P-wave and QRS complex	Sinus node suppression Atrioventricular block Ventricular fibrillation
HYPOKALAEMIA	Prolongation of rapid repolarisation Hyperpolarisation of RMP Increased pacemaker activity in Purkinje and ventricular fibres	U-waves ST-segment and T-wave changes	Atrial and ventricular ectopy Atrial and ventricular tachyarrhythmia Ventricular fibrillation

RMP=resting membrane potential.

In ischaemia, hyperkalaemia at the local tissue level caused by a pathological extracellular shift of K^+ is the major factor contributing to ventricular arrhythmia in this setting. In hypokalaemia, the dispersion of pacemaker activity and the effect on repolarisation are similar to the electrophysiological effects of cardiac glycosides and beta-adrenergic agonists, and it is not surprising that a combination of these factors is associated with an increased incidence of arrhythmia. The increased risk of death in hypertensive patients treated with thiazide diuretics has been attributed to hypokalaemia (and possibly hypomagnesaemia)-induced arrhythmia (Multiple Risk Factor Intervention Trial). Thiazide-induced hypokalaemia ventricular ectopy is worsened by exercise.[8] Hypokalaemia is associated with VF and VT following acute myocardial infarction (AMI). The increased incidence of VF/with a serum K^+ less than 3.5 mmol/L is clearly established and the probability of VT increases as the serum K^+ decreases. During AMI the incidence of VF/VT was 15% at 4.5 mmol/L, 38% at 3.5 mmol/L, 55% at 3.0 mmol/L and 67% at 2.5 mmol/L.[9]

MAGNESIUM

The antiarrhythmic properties of Mg^{2+} are clearly established, but a causal relationship between hypomagnesaemia and arrhythmia is largely circumstantial. Decreased extracellular Mg^{2+} by itself has little effect on the electrophysiological properties of myocytes or the ECG. Hypomagnesaemia has been implicated in the genesis of VT/VF in patients with hypertension and heart failure receiving thiazide or loop diuretics, acute alcohol intoxication or withdrawal and possibly with AMI. The product of K^+ and Mg^{2+} is the best predictor of arrhythmia in hypertensive patients taking thiazide diuretics.[10]

AUTONOMIC NERVOUS SYSTEM AND VENTRICULAR ARRHYTHMIA[11]

The autonomic nervous system, particularly vagal tone, has a significant effect on the occurrence of post myocardial infarction VF, as seen by the following:

- High vagal tone is associated with better outcome and less susceptibility to exercise-induced VF with new ischaemia in animal models.
- Post myocardial infarction exercise training results in an increased vagal tone, which inhibits induceable VF.
- Implantable electrical vagal stimulation and muscarinic agents, including edrophonium, are protective.
- The protection is not heart rate related as the protection remains even when atrial pacing is used to maintain the heart rate.
- The administration of atropine increases the likelihood of developing VF.

Vagal tone can be measured by variability in the heart rate (RR interval) or blood pressure rise induced by the pressor agent phenylephrine. Heart rate variability is considered a measure of tonic vagal activity whereas the phenylephrine method is considered a measure of magnitude of the vagal reflex in response to stimulus. A reduced vagal tone has been found post infarction in humans, which returns to normal over a 3–6-month period. There is no relationship between vagal tone and ejection fraction and the origin of reduced vagal tone post infarction appears to be due to afferent stimulation in response to necrotic tissue and impaired cardiac contractile geometry. This reduced vagal tone has also been shown to be predictive of mortality and inductility of arrhythmia at electrophysiological study (EPS).

HETEROGENEITY OF REPOLARISATION: T-WAVE ALTERNANS[12]

Regional differences in repolarisation are associated with preconditions for conduction block, re-entry and life-threatening arrhythmias. This heterogeneity is seen in settings of impaired sarcoplasmic reticulum uptake of Ca^{2+} during ischaemia, drug proarrhythmia and congenital prolonged QT syndromes. In addition to prolonged QTc, ECG changes show variability of T-waves. This variability can manifest as visible T-wave alternans (TWA), defined as a beat-to-beat alternation in the

morphology and amplitude of the ST segment or T-wave (**Fig. 22.5**).

Computerised analytical methods for detecting non-visual TWA in the microvolt range have been developed for predicting risk of ventricular tachyarrhythmia, sudden death and need for implantable cardioverter-defibrillators. The utility of TWA appears to be better than left ventricular function. TWA can be quantified as the moving average of beat-to-beat variation in T-wave amplitude (**Fig. 22.6**).

TWA may find a role in guiding drug therapy as a marker of antiarrhythmic effect and proarrhythmia.

PROARRHYTHMIC EFFECTS OF ANTIARRHYTHMIC DRUGS[13,14]

Accompanying proarrhythmia with the use of antiarrhythmic drugs is increasingly recognised. The 'quinidine syncope' due to VF and polymorphic VT at therapeutic concentrations was also seen with disopyramide. The Cardiac Arrhythmia Suppression Trial (CAST) clearly defined the magnitude of this deleterious side-effect in drugs that were previously perceived to be of benefit.[15] This study, which involved flecainide, encainide and morizicine (a class IA drug), was terminated early because of adverse outcome in the flecainide and encainide groups (relative risk of arrhythmic death or non-fatal cardiac arrest of 3.6, 95% confidence interval (CI) 1.7–8.5). Proarrhythmia is reported between 5.9% and 15.8% depending on agent, clinical setting and definition of proarrhythmia, and now considered ubiquitous with all antiarrhythmic drugs.

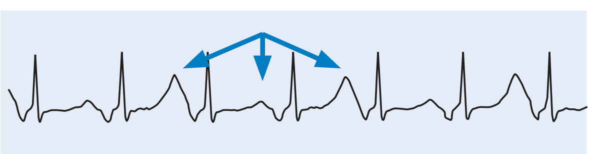

Figure 22.5 Visible T-wave alternans and prolonged QT associated with heterogeneity of repolarisation.

Proarrhythmia has been defined as an increase in frequency of ventricular ectopic beat (VEB) or aggravation of the target arrhythmia on Holter monitor or exercise test. Manifestations of proarrhythmia not only include VEB, monomorphic and polymorphic VT and VF, but also bradyarrhythmias and Afl with 1:1 AV conduction. Most proarrhythmic events occur soon after starting the drug, but late arrhythmias are also a significant problem.

Proarrhythmia appears to be correlated with the degree of drug-induced QT prolongation, T-wave variability and characteristics of sodium channel blockade by the agent involved. Sodium-channel-blocking agents with a long time constant for recovery of the sodium channel blockade cause more pronounced blockade, even at slow heart rates, slow conduction to a greater extent and are associated with greater proarrhythmia. Agents with a short time constant of sodium channel blockade, where sodium channel blockade is more pronounced at fast heart rates (e.g. class IB: lidocaine and mexiletine), are less proarrhythmic than drugs with long time constants (e.g. class IC: flecainide and propafenone). Class III drugs and quinidine proarrhythmia correlate with degree of QT prolongation.

The mechanism of drug proarrhythmia is probably via both slowing of conduction and abnormal automaticity. Paradoxically slowing conduction, which may block a re-entry circuit, may also create the very substrate needed for re-entry, unidirectional block and an excitable gap. The existence of a re-entrant circuit requires the circulating wave front of the impulse not to catch up with the refractory tissue behind the

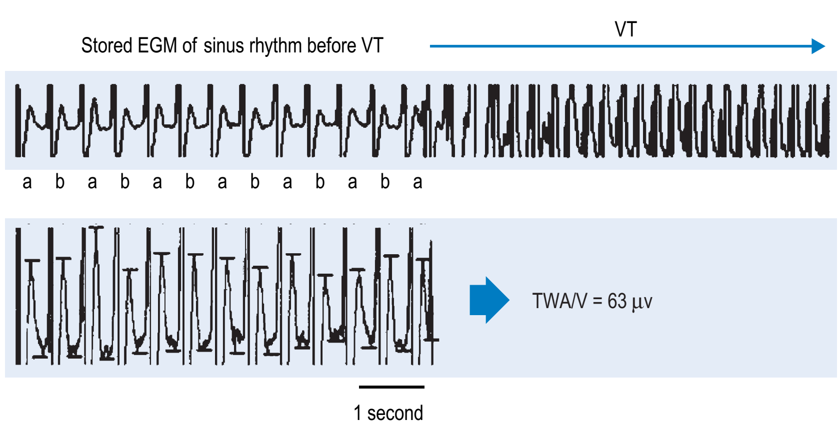

Figure 22.6 Example of heterogeneous repolarisation resulting in beat-to-beat microvolt fluctuation in T-wave amplitude measured by the Modified Moving Average method at 63 microvolts heralds the onset of ventricular tachycardia. *(From American Heart Association, with permission.)*

tail. Re-entry is more likely to occur with a shorter refractory period and reduced conduction velocity (**Fig. 22.7**).[11]

Increasing conduction velocity is an ideal antiarrhythmic property but there are no antiarrhythmic drugs that accelerate conduction. However antiarrhythmic drugs readily slow conduction and the degree of conduction slowing and therefore proarrhythmia tendency correlates with the potency of antiarrhythmic properties.

Prolonging the refractory period is also an ideal antiarrhythmic property, which increases the likelihood of abolishing any excitable gap by ensuring the wave front of a re-entrant circuit meets refractory tissue. The potency of class IA and III antiarrhythmic agents is dependent on the prolongation of the refractory period. This property is also protective against proarrhythmia due to re-entry mechanism. The effect of class IB agents on shortening the refractory period will contribute to proarrhythmia by this mechanism in this class.

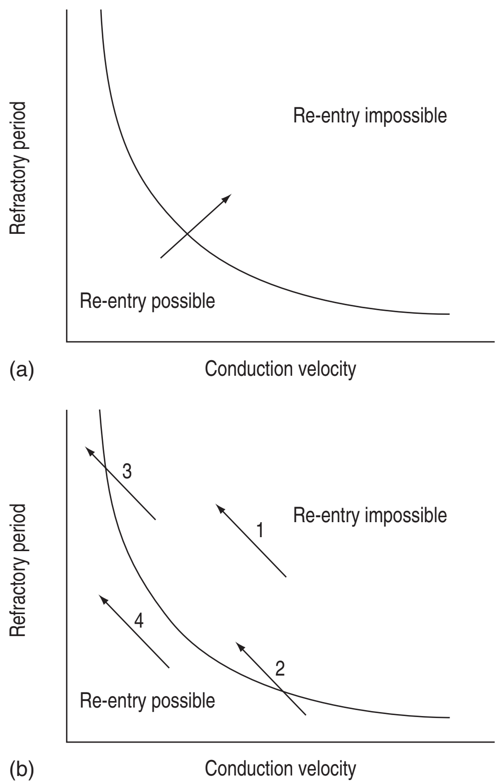

Figure 22.7 (a) Graph of refractory period of an excitable gap versus its conduction velocity around a theoretical re-entrant circuit. When conduction velocity is high enough so that refractory period of excitable gap exceeds circuit time, re-entry is impossible. Arrow demonstrates the action of an 'ideal' antiarrhythmic drug, which prolongs the refractory period and increases conduction velocity. (b) With antiarrhythmic drugs that increase the refractory period and slow conduction, the net effect of an antiarrhythmic drug may have no effect on proarrhythmia (arrows 1 and 4), decrease proarrhythmia (arrow 2) or increase proarrhythmia (arrow 3) depending on properties of a potential re-entrant circuit. *(Adapted from Schwartz PJ, La Rovere MT, Vanoli E. Autonomic nervous system and sudden cardiac death. Circulation 1992;85(Suppl 1):77–91, with permission.)*

Surface mapping of the heart has been used to quantify proarrhythmic effect. The scale of potency of proarrhythmia has been found to be:

flecainide > propafenone > quinidine > disopyramide > procainamide > mexiletine > lidocaine > sotalol.

Amiodarone was not included in this study but presumably its proarrhythmic potential is similar to other class III agents and less than the class I agents.

Antiarrhythmic drugs are effective at suppressing abnormal automaticity, with the exception of triggered automaticity due to EAD. Class IA, class III and many non-antiarrhythmic drugs can produce proarrhythmia via EAD. These drugs increase not only the frequency of EAD, but also the likelihood of them leading to triggered tachyarrhythmia. Slowing repolarisation, which leads to QT prolongation and slower heart rate, is central to this increased frequency and sensitivity to EAD. EAD manifests as prominent and bizarre T-U waves on the ECG and, if triggered activity results, VEB and ventricular tachyarrhythmia may occur. Torsade de pointes is the classical resulting arrhythmia, although less classical polymorphic VT and VF can result. Risk of proarrhythmia via this mechanism correlates with the degree of QT prolongation.

All antiarrhythmic drugs are capable of producing bradyarrhythmia via decreasing normal automaticity and slowing conduction. Digoxin can be proarrhythmic via the production of triggered activity due to DAD.

Antiarrhythmic drug proarrhythmia is facilitated by several factors, which are frequently found in patients on antiarrhythmic drugs or with heart disease (**Box 22.1**).

Box 22.1 Factors facilitating antiarrhythmic drug proarrhythmia[13]

- Toxic blood levels due to excessive dose or reduced clearance from old age, heart failure, renal disease or hepatic disease
- Severe left ventricular dysfunction; ejection fraction less than 35%
- Pre-existing arrhythmia or arrhythmia substrate
- Digoxin therapy
- Hypokalaemia or hypomagnesaemia
- Bradycardia
- Combinations of antiarrhythmic drugs and concomitant drugs with similar toxicity

MANAGEMENT OF THE PATIENT WITH A CARDIAC ARRHYTHMIA

HISTORY AND PHYSICAL EXAMINATION

A careful history is important. Specific questions should confirm or exclude palpitations, syncope, chest pain, shortness of breath, ischaemic heart disease (especially previous myocardial infarction), congestive cardiac failure, valvular heart disease, thyrotoxicosis and diuretic therapy without adequate potassium supplements. A family history is helpful for arrhythmias associated with inherited disorders (e.g. LQTS and hypertrophic obstructive cardiomyopathy). The physical examination looks for underlying structural heart disease and signs to assist diagnosis, and assesses haemodynamic consequences of the arrhythmia.

VAGAL MANOEUVRES

Vagal manoeuvres may be undertaken during examination. These reflexly increase vagal tone, thereby prolonging AV node conduction and refractoriness. The effect may be:

- transient slowing of sinus tachycardia as SA nodal discharge rate is slowed
- termination of AV nodal re-entry tachycardia (AVNRT) and AV re-entry tachycardia (AVRT)
- unmasking (but not reversion) of atrial tachycardia, flutter (**Fig. 22.8**) and fibrillation.

VT is not affected. Carotid sinus massage has been most commonly used. Valsalva manoeuvre or iced water to the face may be useful. Eyeball pressure should be avoided as eye damage may result.

Increasingly the Valsalva manoeuvre is recommended. Maximum vagal effect is achieved with supine positioning and a Valsalva manoeuvre of 15 seconds duration and a pressure of 40 mmHg (5.32 kPa) with an open glottis. An adequate Valsalva manoeuvre method can be achieved by getting the patient to blow into a 10 mL syringe in an attempt to move the plunger.

INVESTIGATIONS

A 12-lead ECG should be recorded with a longer rhythm strip (usually lead II or V_1). If P-waves are not visible, atrial activity may be recorded using an oesophageal electrode or pacing lead, or via a central venous catheter or the right atrial injectate port of a pulmonary artery catheter, using 20% saline and a bedside monitor.[16]

Holter monitoring requires prolonged (usually 24–72 hours), non-invasive, ambulatory ECG monitoring, sometimes combined with exercise testing. EPS, which involves invasive electrophysiological testing with programmed electrical stimulation, attempts to reproduce the spontaneously occurring arrhythmia.[17,18] EPS is not clearly superior to Holter monitoring in evaluating drug treatment for ventricular arrhythmias. Other investigative techniques being studied include signal-averaged ECG, heart rate variability and electrical alternans measurement.[11,19]

MANAGEMENT OF SPECIFIC ARRHYTHMIAS

Treatment has two aspects: acute termination of the arrhythmia and long-term prophylaxis. The decision whether to treat depends on the rhythm diagnosis, haemodynamic consequences, aetiology of the arrhythmia and the prognosis (e.g. risks of sudden death or long-term complications).

ECTOPIC BEATS

These are premature impulses originating from the atria, AV junction or ventricles. The coupling interval (time between the ectopic and the preceding beat) is shorter than the cycle duration of the dominant rhythm.

PREMATURE VENTRICULAR ECTOPIC BEATS

These are also known as ventricular premature beats and ventricular premature complexes. The ventricle is not activated by the normal rapidly conducting bundle branches, and a wide QRS complex results from slow ventricular conduction.

ECG

There is no preceding P-wave.

- Premature complexes occur before the next expected QRS.
- QRS is wide (>120 ms).

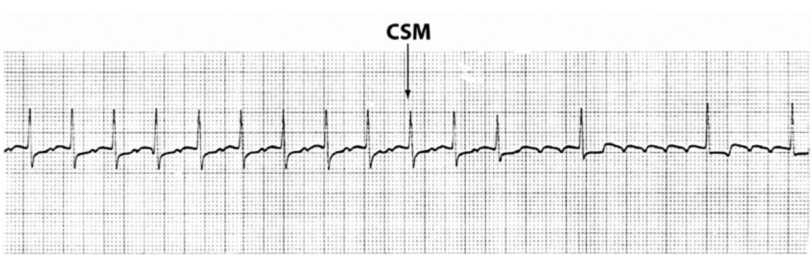

Figure 22.8 Atrial flutter with 2:1 atrioventricular (AV) block. Carotid sinus massage (CSM) increases AV block to 4:1 then 6:1.

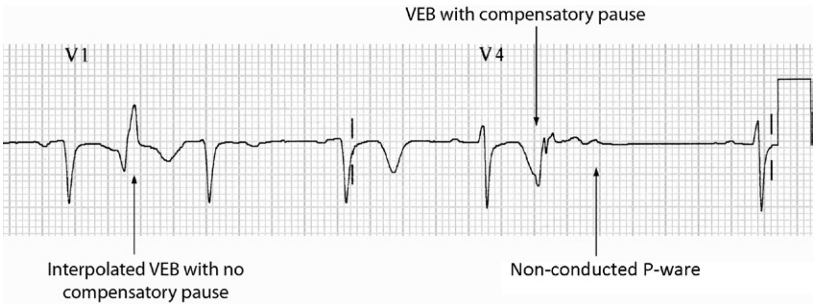

Figure 22.9 Sinus rhythm with an interpolated ventricular ectopic beat (VEB) without a compensatory pause and a VEB with a following non-conducted P-wave, resulting in a compensatory pause.

- T-wave of opposite polarity to the QRS (**Fig. 22.9**).
- VEB is not conducted retrogradely to the SA node.
- SA node is therefore not reset, and there is temporary AV dissociation with a full compensatory pause; the interval between the normal QRS complexes on either side of the VEB will usually be twice that of the dominant sinus rhythm.

Occasionally VEBs may not produce any pause, and are said to be interpolated (see Fig. 22.9). Interpolated VEBs occur when the background sinus rhythm is slow. The retrograde conduction into the AV node renders it partially refractory to the next impulse and its conduction through the AV node is slowed and the PR interval is prolonged. A VEB following each sinus beat is ventricular bigeminy. Ventricular trigeminy refers to recurring sequences of a VEB followed by two sinus beats. Two VEBs in succession are a couplet, and three, a triplet.

CLINICAL

Even when frequent, complex, or in short runs of non-sustained VT, VEBs are not associated with risk of sudden death in asymptomatic healthy adults.[20] However, there is increased risk of cardiovascular death with:

- *exercise-induced VEB:* risk of death 2.53 (95% CI 1.65–3.88)[21]
- *AMI and VEB:* frequent and complex VEBs often precede VF or sustained VT and are a marker of risk of subsequent SCD.

Apart from ischaemic heart disease, VEB may be associated with cardiomyopathy, valvular disease, myocarditis and non-cardiac precipitating factors (e.g. electrolyte and acid–base disturbances, hypoxia and drugs such as digoxin).

TREATMENT

Drug treatment of VEB is rarely indicated and may be dangerous.

- Correct potassium and magnesium.
- Severely symptomatic patients with frequent complex VEB may benefit from judicious beta blockade.
- The underlying cause of VEB is often more clinically relevant than the arrhythmia. Following myocardial infarction, beta-adrenergic blockers, which are indicated for long-term benefit, will also likely suppress VEB.
- Prophylactic lidocaine following AMI will increase total mortality and has been abandoned.[22,23]
- Attempts at long-term VEB suppression with class IC agents (flecainide and encainide), even if successful, increase mortality.[15]

Box 22.2 Classification of supraventricular tachycardia

Atrioventricular (AV) node dependent
AV nodal re-entry tachycardia: re-entry within the AV node
AV re-entry tachycardia: re-entry includes accessory pathway between atria and ventricles
Accelerated idionodal rhythm: increased automaticity of AV node

AV node independent
Atrial flutter: re-entry confined to atria
Atrial fibrillation: multiple re-entry circuits confined to atria
Unifocal atrial tachycardia: usually due to increased automaticity
Multifocal atrial tachycardia: increased automaticity or triggered activity
Others: sinus node re-entry tachycardia

SUPRAVENTRICULAR TACHYCARDIAS[24,25] (BOX 22.2)

Supraventricular tachycardia (SVT) is any tachycardia that requires atrial or AV nodal tissue for initiation and maintenance.

- SVTs are usually conducted rapidly through the bundle branches so that QRS complexes are narrow.
- All narrow-complex tachycardia are SVT and wide-complex tachycardia are usually ventricular.
- However, SVT may be wide complex in the setting of bundle branch block (BBB) and pre-excitation.

A clinically useful classification divides SVTs into AV node-dependent and AV node-independent. Distinguishing between AV node-dependent and independent SVTs can be difficult. Vagal manoeuvres or drugs that prolong AV nodal refractoriness (e.g. adenosine) may assist in diagnosis:

- Temporary AV block with unchanged atrial rate indicates AV node independence.
- Slowing or reversion of the tachycardia diagnoses AV dependence.

AV NODE-DEPENDENT SVT

In these SVTs, sometimes referred to as junctional tachycardia, the re-entry circuit or ectopic focus involves the AV node or junction. Blocking the AV node with drugs such as adenosine or vagal manoeuvres will terminate these SVTs.

AV NODE-INDEPENDENT SVT

Also referred to as atrial tachycardia, the atrial tissue only is required for the initiation and maintenance of the tachycardia. Blocking the AV node will not terminate these SVTs; it will merely slow the ventricular rate.

AV NODAL RE-ENTRY TACHYCARDIA (AVNRT) (FIG. 22.10)

Re-entry tachycardia is confined to the AV node. Antegrade conduction to the ventricles usually occurs over the slow pathway and retrograde conduction over the fast pathway.

ECG

There is regular narrow-complex tachycardia (140–220 beats/min) with abrupt onset and termination. P-waves are not usually observed as they are buried in the QRS complexes (Fig. 22.11).

CLINICAL

AVNRT is a common arrhythmia that is not usually associated with structural heart disease. The major symptom is palpitations.

TREATMENT

Vagal manoeuvres slow conduction through the AV node and may 'break' the tachycardia. If vagal manoeuvres fail, adenosine is the drug of choice and nearly all AVNRT will revert with adenosine.[23,26] Verapamil has been used in the past, but causes hypotension, which may be prolonged if cardiac function is depressed or patients are receiving beta-adrenergic blockers. Sotalol, amiodarone and flecainide may also be effective but are rarely used. Rapid atrial pacing will usually terminate AVNRT but is rarely needed.

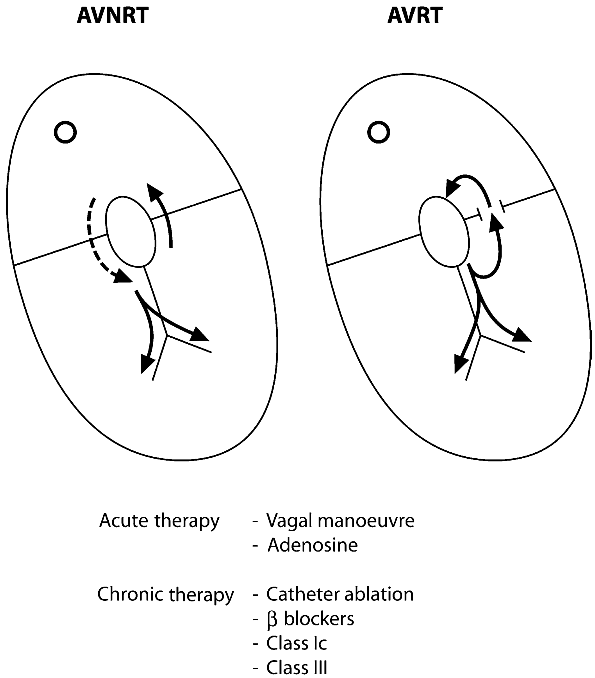

Figure 22.10 Atrioventricular nodal re-entry tachycardia (AVNRT) has both pathways in the AV node. The conduction occurs over the slow pathway and retrogradely over the fast pathway. AV re-entry tachycardia (AVRT) involves antegrade conduction through the AV node and retrograde conduction through an accessory pathway.

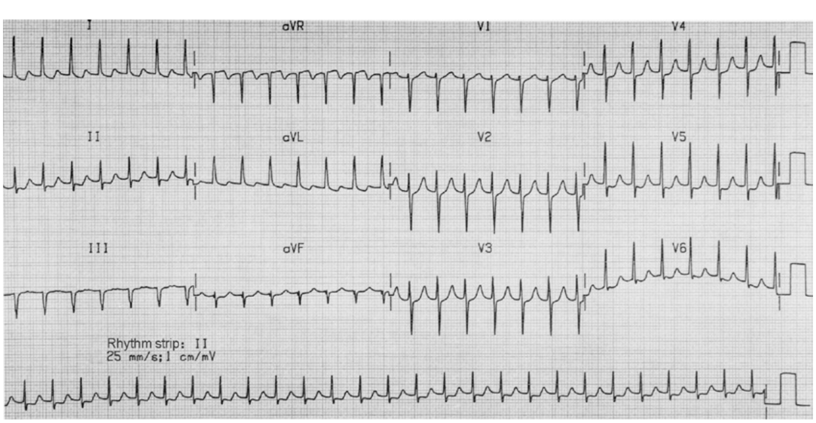

Figure 22.11 Atrioventricular nodal re-entry tachycardia (AVNRT). Narrow QRS tachycardia at 160 beats/min. P-waves are not apparent and are buried in the QRS complex.

Cardioversion is occasionally necessary when drugs are ineffective or when severe haemodynamic instability is present.

PREVENTION

Troublesome recurring episodes of AVNRT can be cured by radiofrequency ablation, using a transvenous catheter to interrupt the re-entrant circuit permanently.[27]

AV RE-ENTRY TACHYCARDIA (SEE FIG. 22.10)

The re-entry pathway consists of the AV node and an accessory pathway, which bypasses the AV node. The accessory pathway may be evident during sinus rhythm, with the ECG showing pre-excitation: short PR interval, delta wave and widening of the QRS (see WPW, below, under Pre-excitation syndrome). However, in 25% of cases, the accessory pathway conducts only retrogradely from ventricle to atria and the ECG pre-excitation will be concealed in sinus rhythm. Orthodromic AVRT, with antegrade nodal and retrograde accessory pathway circuit, is the most common regular SVT in patients with accessory pathway.

ECG

The ECG is similar to AVNRT. The length of the re-entry circuit is, however, greater and the accessory AV pathway is some distance from the AV node. It therefore takes longer for the impulse to be conducted backwards to the atria, and so the retrograde P-wave usually occurs after the QRS, sometimes at some distance, and is inverted in leads II, III and aVF (**Figs 22.12** and **22.13**).

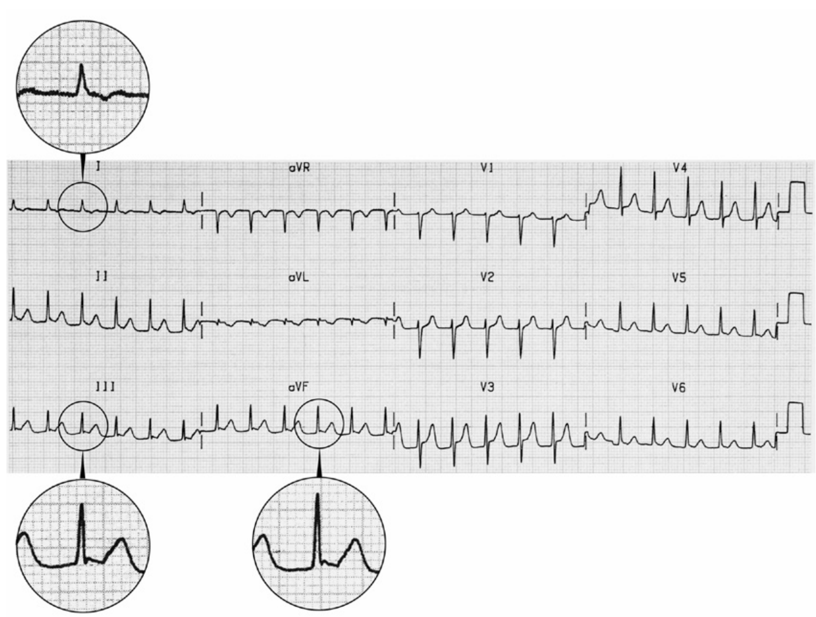

Figure 22.12 Atrioventricular re-entry tachycardia (AVRT). Narrow QRS tachycardia at 135 beats/min. Inverted P-wave in leads I, II, III and aVF just following the QRS complex.

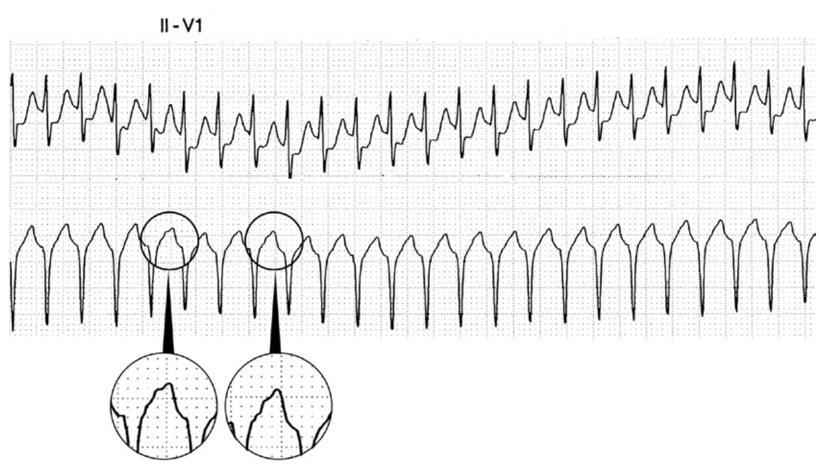

Figure 22.13 Atrioventricular re-entry tachycardia (AVRT). Rate is 214 beats/min. P-wave deflection is just seen on the upslope of the T-wave in lead V_1.

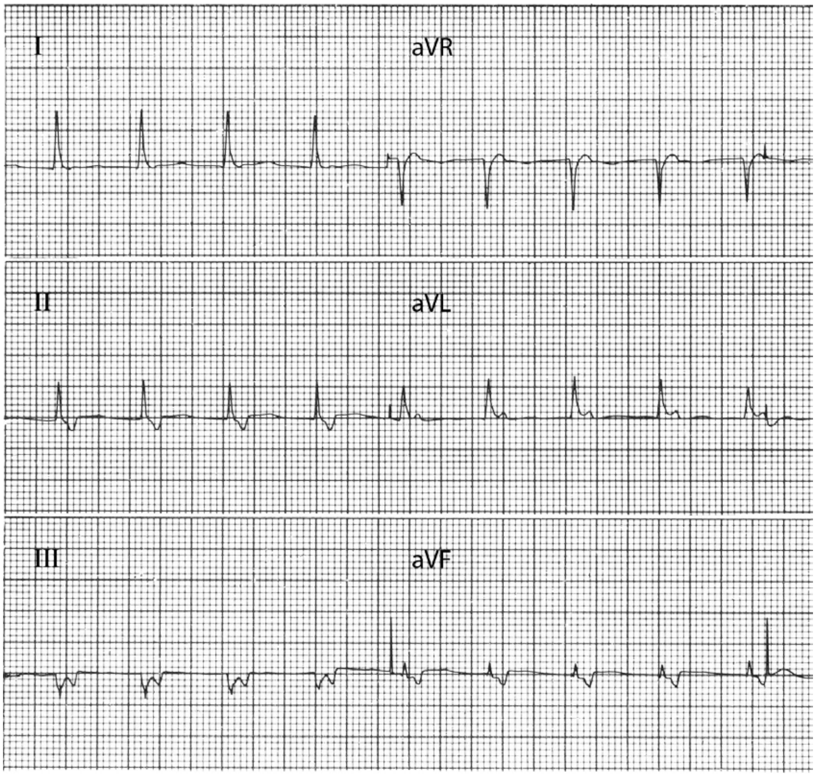

Figure 22.14 Accelerated idionodal rhythm: 105 beats/min. Inverted P-wave is immediately following the QRS complex in leads II, III and aVF.

CLINICAL

AVRT is similar to AVNRT, although antegrade conduction over the accessory pathway may be very rapid with WPW, if AF occurs.

TREATMENT[23,26]

Acute treatment is identical to AVNRT, but verapamil should be avoided in WPW syndrome, as it may block the AV node, facilitating very rapid conduction to the ventricles via the accessory pathway.[28]

PREVENTION

Drugs such as sotalol and flecainide may prevent recurrence of the tachycardia. Radiofrequency ablation of the accessory pathway is usually curative.[27]

ACCELERATED IDIONODAL RHYTHM

Increased automaticity of the AV junction (above the inherent discharge rate of 40–60 beats/min) is the usual cause of this arrhythmia. The often-used term 'non-paroxysmal AV junctional tachycardia' is cumbersome and misleading: junctional rate is commonly 60–100 beats/min, not strictly a tachycardia. AV dissociation is often present, but there may be synchronisation of the two pacemakers – so-called isorhythmic dissociation.

ECG

There are narrow complexes on the ECG at a regular rate (60–130 beats/min) (**Fig. 22.14**), often with independent atrial activity. With isorhythmic dissociation, the P-wave is either fixed relative to the QRS complex (usually just after) or oscillates to and fro across the QRS in a rhythmical manner.

CLINICAL

It may be observed in normal persons, but is often associated with structural heart disease, especially following inferior myocardial infarction. Digoxin intoxication is another important cause.

TREATMENT

In most cases, the rhythm is transient and well tolerated, and no treatment is required. Treatment is otherwise directed towards the underlying cause.

UNIFOCAL ATRIAL TACHYCARDIA

This is sometimes called ectopic atrial tachycardia to distinguish it from the atrial tachycardia (referring collectively to unifocal atrial tachycardia, Afl and AF). However, it is inappropriate to call atrial tachycardia paroxysmal atrial tachycardia. Paroxysmal, by definition, indicates an abrupt onset and termination, which

Figure 22.15 Unifocal atrial tachycardia with 1 : 1 atrioventricular conduction; rate is 140 beats/min. Large, inverted P-waves are seen in lead II.

applies less commonly to unifocal atrial tachycardia. Vagal manoeuvres will not terminate this arrhythmia, but AV block may be induced, or increased if already present.

ECG

P-wave morphology is abnormal but monomorphic. Atrial rate is often 130–160 beats/min, and may occasionally exceed 200 beats/min. Atrial rate distinguishes unifocal atrial tachycardia from atrial flutter (Afl), with Afl greater than 250 beats/min. The QRS complexes will usually be narrow (**Fig. 22.15**). AV block is common (**Fig. 22.16**).

CLINICAL

Digitalis intoxication is the most common cause, especially when AV block is present. Other causes include myocardial infarction, chronic lung disease and metabolic disturbances.

TREATMENT[23]

If applicable, digitalis is stopped and the toxicity treated. Otherwise digoxin may be used to control the ventricular rate. Beta-adrenergic blockers or amiodarone are alternatives. Rapid atrial pacing may be ineffective if the arrhythmia is due to increased automaticity, although it may increase AV block, thereby slowing ventricular rate. Synchronised DC shock may be necessary, but is avoided if digitalis intoxication is suspected.

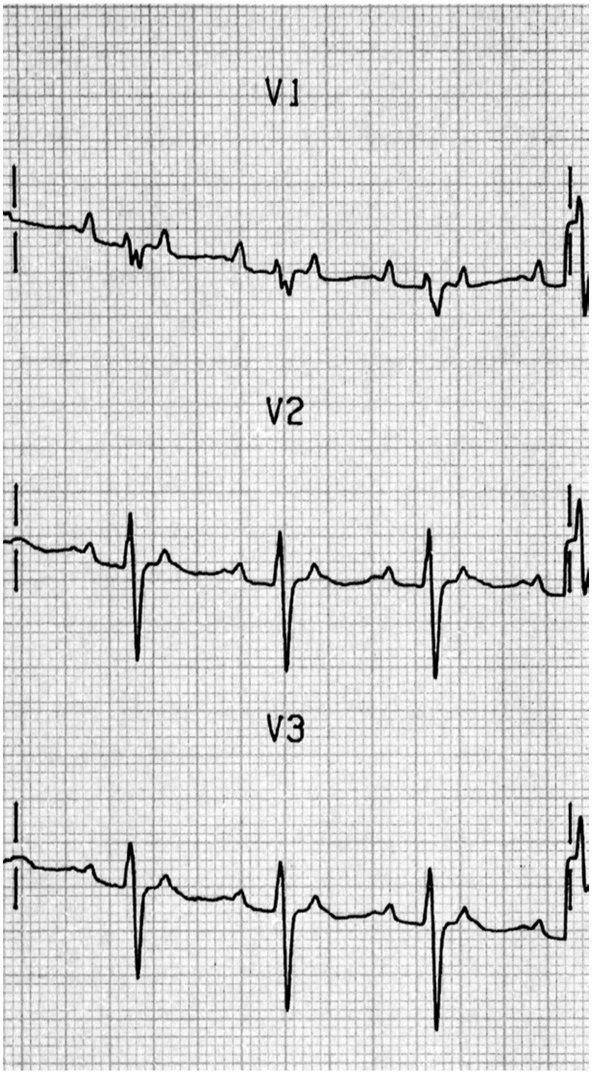

Figure 22.16 Unifocal atrial tachycardia with 2 : 1 atrioventricular conduction. Atrial rate is 170 beats/min.

MULTIFOCAL ATRIAL TACHYCARDIA[29]

Multifocal atrial tachycardia (MAT) is defined as an atrial rhythm, with a rate greater than 100 beats/min, with organised, discrete non-sinus P-waves having at least three different forms in the same ECG trace. The baseline between P-waves is isoelectric, and the PP, PR and RR intervals are irregular. This is an uncommon arrhythmia, also known as chaotic or mixed atrial tachycardia.

ECG

There are irregular atrial rates, usually 100–130 beats/min, with varying P-wave morphology (at least three different P-wave morphologies and varying PR interval) and some degree of AV block (**Fig. 22.17**). Most P-waves are conducted to the ventricles, usually with narrow QRS complexes.

CLINICAL

MAT is often misdiagnosed and inappropriately treated as AF. This rhythm occurs most commonly in critically ill elderly patients with chronic lung disease and cor pulmonale, and is associated with a very high mortality

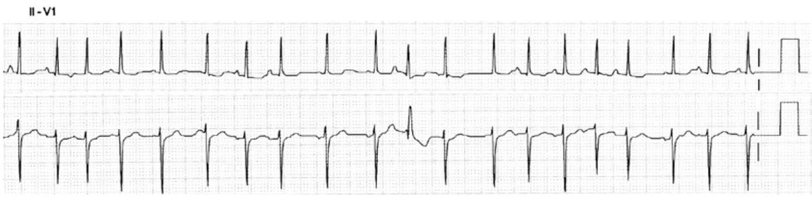

Figure 22.17 Multifocal atrial tachycardia with the rate about 130 beats/min. There is varying P-wave morphology and PR intervals. Note the wide complex preceded by a P-wave. The aberrant intraventricular conduction is related to the long–short cycle length sequence.

from underlying disease. Theophylline has been implicated as a precipitating cause, and rarely digoxin.

TREATMENT

Treatment should correct the underlying cause (e.g. treatment of cardiorespiratory failure, electrolyte and acid–base abnormalities and theophylline toxicity). Spontaneous reversion is common, and few patients require antiarrhythmic therapy. Magnesium is the drug of choice for acute control.[30] Beta blockers are probably more effective than diltiazem, but because of the common association of MAT with obstructive lung disease have limited utility.[31] Digoxin and cardioversion are ineffective, which highlights the need to differentiate MAT from AF. Longer-term control is best achieved with diltiazem in patients with good left ventricular (LV) function and amiodarone in those without.

ATRIAL FLUTTER[32,33]

Afl is an intra-atrial macro-re-entrant arrhythmia with an impulse and contraction wave circulating the atrium at rates of 250–350 beats/min, and in most cases, close to 300 beats/min. Afl occurs at about one-tenth the frequency of AF, often coexisting with AF, with 56% eventually developing AF. Afl is more common in males and incidence increases with age. Conditions associated with Afl are shown in **Box 22.3**.

AV conduction in Afl is usually 2:1, resulting in a regular rhythm, but conduction may be irregular. Rarely 1:1 AV conduction can occur and may be lethal.

Afl is classified according to the anatomical pathway of the circuit. Right atrial cavotricuspid-isthmus-dependent flutter involving a circuit bounded by tricuspid orifice, vena cavae orifices, Eustachian and crista terminalis, is overwhelmingly most common. From a left anterior oblique view, this counter-clock-wise circuit makes up 90% of Afl cases and is classically referred to as 'typical'. Circuits can also be clock-wise, involve the right atrium but with different circuits relating to scars or be located in the left atrium.

ECG

'Typical' Afl waves (characteristic sawtooth appearance with no isoelectric baseline) are best seen in V_1, and are negative in inferior leads with positive waves in V_1 that transition to negative in V_6 (**Fig. 22.18**). Rapid QRS waves may obscure typical flutter waves, and vagal manoeuvres may unmask them (see Fig. 22.8). AV conduction block (usually 2:1) is usually present, so that alternate flutter waves are conducted to the ventricles, with a ventricular rate close to 150 beats/min. Frequently flutter waves are not obvious and a ventricular rate of 150 beats/min leads to the presumption of Afl (**Fig. 22.19**). 'Non-typical' Afl, normally associated with scar or structural abnormalies often results in greater atrial and ventricular rates (**Fig. 22.20**). Treatment with drugs that affect AV node conduction may lead to higher degrees of AV block (**Fig. 22.21**) and/or variable AV block with irregular QRS duration. Afl with 1:1 conduction is associated with sympathetic overactivity, class I antiarrhythmic drugs (which slow atrial discharge rate to around 200 beats/min, thereby allowing each atrial impulse to be conducted) or Wolff–Parkinson–White syndrome and a short antegrade refractory period of the accessory pathway (**Fig. 22.22**). QRS complexes are usually narrow, as conduction through the bundle branches is normal.

Box 22.3 Conditions associated with atrial flutter

- Valvular heart disease
- Myocardial infarction
- Pericardial disease
- Cardiac tumours
- Hypertrophic cardiomyopathy
- Congenital heart disease
- Post surgical repair of congenital heart disease
- Post cardiothoracic surgery
- Post major non-cardiac surgery
- Severe pulmonary disease
- Pulmonary embolus
- Thyrotoxicosis
- Acute alcohol intoxication

TREATMENT[23,33]

Drug therapy has proven to be notoriously unsuccessful for Afl and large doses of AV blockers are often needed for rate control. Although no drug will reliably terminate Afl, ibutilide and dofetilide have been shown to be most likely to result in pharmacological reversion.

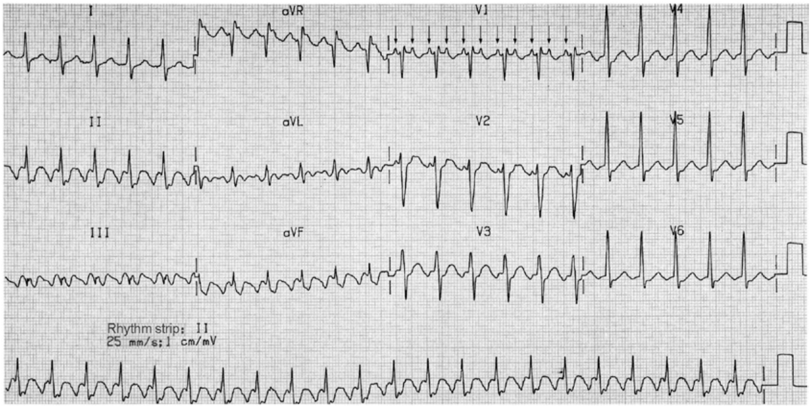

Figure 22.18 Atrial flutter with 2:1 atrioventricular conduction. Atrial rate is 270 beats/min (arrows V_1) and ventricular 135 beats/min. Characteristic 'sawtooth' inverted flutter waves are evident in leads II, III and aVF.

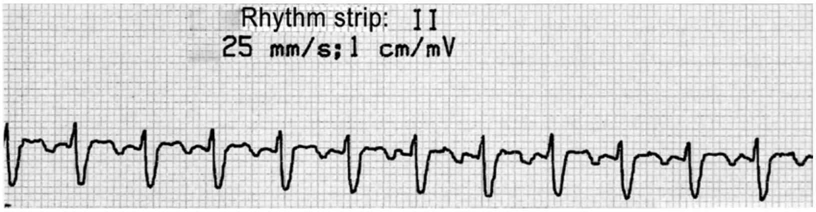

Figure 22.19 Atrial flutter with 2:1 atrioventricular (AV) conduction. Inverted flutter waves are difficult to differentiate from T-waves. Rate of 144 beats/min confirms atrial flutter with 2:1 AV conduction.

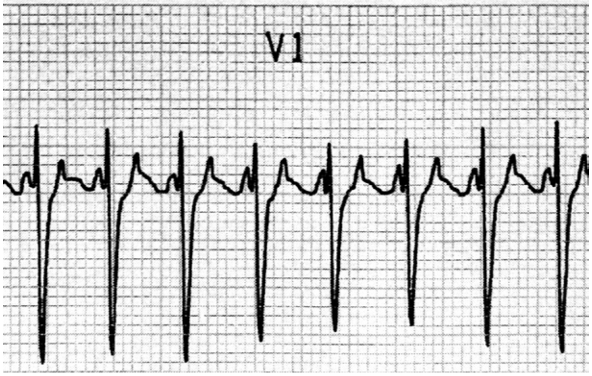

Figure 22.20 Atrial flutter with 2:1 atrioventricular conduction. Type II atrial flutter is confirmed by the rapid atrial rate of 380 beats/min.

Flecainide and procainamide may also occasionally be effective at terminating Afl. Initial attempts at slowing ventricular rate by drugs that will increase the degree of AV block are worthwhile in the first instance. Drugs such as digoxin, diltiazem, beta-adrenergic blockers, sotalol and amiodarone may be tried; the choice depends on LV function. It is important to remember class IA and IC drugs may lead to 1:1 AV conduction. Class I drugs should probably be avoided unless ventricular response has been slowed with calcium channel or beta-adrenergic blocking drugs.

Synchronised DC cardioversion, often with low energies (25–50 J), is a reliable treatment option and is often required. Rapid atrial pacing faster than the flutter rate will terminate 'typical' Afl in most patients.

Anticoagulation guidelines are the same as those for AF, although there are less supporting data.

PREVENTION

Prevention is difficult. Drugs used include sotalol and amiodarone at low doses. Class IC agents (e.g. flecainide) may be used in patients without significant structural heart disease. Increasingly, recurrent or refractory Afl may be cured by radiofrequency ablation, which creates a linear lesion between the inferior tricuspid annulus and the Eustachian ridge at the anterior margin of the inferior vena cava to interrupt the re-entry circuit.[27] 'Typical' Afl is most amendable to circuit ablation.

ATRIAL FIBRILLATION[34,35]

AF is the most common arrhythmia requiring treatment and/or hospital admission. The incidence increases with age: 5% of individuals over 70 years have this arrhythmia. There is also an age-independent increase in frequency owing to increasing obesity and obstructive sleep apnoea. LV dyfunction increases risk of AF (4.5-fold in men and 5.9 in women) with atrial stretch and fibrosis causing electrical and atrial ionic channel remodelling.

AF is common in:

- congestive cardiac failure (40%)
- coronary artery bypass grafting (25–50%)
- critically ill patients (15%).

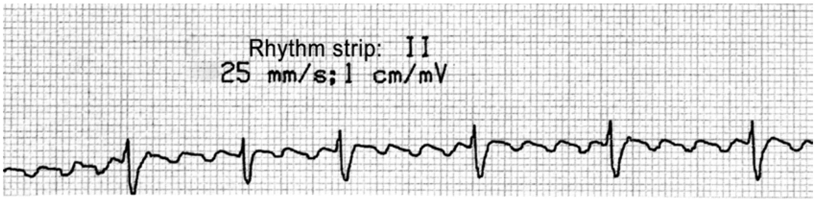

Figure 22.21 Atrial flutter varying between 3 : 1 and 4 : 1 atrioventricular (AV) conduction due to drug effect slowing AV node conduction.

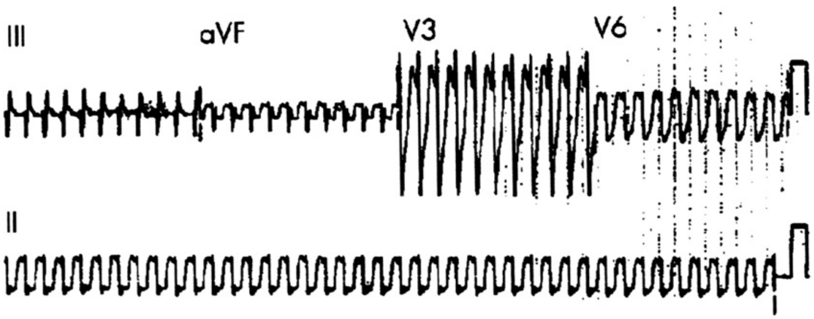

Figure 22.22 Atrial flutter with 1 : 1 conduction with a rate of 240 beats/min. Up-sloping of ST segment is easily mistaken as part of the QRS complex, giving the appearance of a broad QRS tachycardia in some leads. Lead III shows true narrow width of QRS complex.

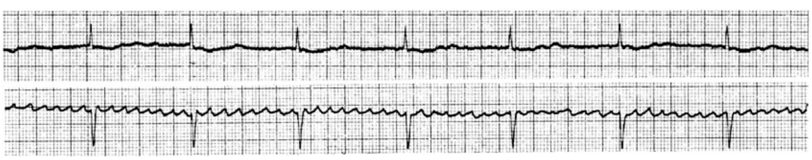

Figure 22.23 Atrial fibrillation. Irregular fibrillation waves with varying amplitude and morphology.

Figure 22.24 Atrial fibrillation with rapid ventricular rate. Ventricular irregularity and fibrillation waves are less evident when the rate is rapid.

Idiopathic or lone AF (i.e. with no structural heart disease or precipitating factor) in someone aged less than 60 years has an excellent prognosis; however, AF developing after cardiac surgery, for instance, is associated with increased stroke, life-threatening arrhythmias and longer hospital stays.

ECG

Atrial activity is chaotic with rapid (350–600 beats/min) and irregular depolarisation varying in amplitude and morphology (fibrillation waves). Ventricular response is irregularly irregular (**Fig. 22.23**). Most atrial impulses are not conducted to the ventricles; resulting in an untreated ventricular rate of 100–180 beats/min. QRS complexes will usually be narrow. When the ventricular rate is very rapid or very slow, ventricular irregularity may be missed (**Fig. 22.24**).

CLINICAL

AF is more common in patients with underlying heart disease (particularly those with a dilated left atrium) and abnormal atrial electrophysiology. Causes include ischaemic and valvular heart disease, pericarditis, hypertension, cardiac failure, thyrotoxicosis and alcohol abuse. AF may also occur after cardiac surgery and thoracotomy. AF can be chronic, or intermittent with paroxysmal attacks. Chronic AF has a poorer prognosis.

AF is associated with:

- *adverse haemodynamic effects:* rapid ventricular rate and loss of atrial systole may increase pulmonary capillary wedge pressure, while stroke volume and cardiac output decline
- systemic embolism and stroke
- *tachycardiomyopathy:* reversible global cardiomyopathy secondary to rapid heart rate. Assessing LV

function with echocardiogram before and after AV node ablation for AF refractory to medical therapy suggests that 10% of patients with AF have AF-induced tachycardiomyopathy.[36]

TREATMENT[23,37,38]

The goals of treatment include ventricular rate control, conversion to sinus rhythm, maintenance of sinus rhythm and anticoagulation where appropriate. There is increasing evidence available on the 'rate versus rhythm' control debate. Results from several recent major studies have challenged the previous belief that achievement of sinus rhythm is important in the long term (**Table 22.5**). When comparing control of ventricular rate versus reversion to sinus rhythm no clear survival benefit is apparent. However composite end-points of death, stroke and recurrent hospitalisation favour rate control only.[39–42]

The possible reasons why rhythm control has not been shown to be superior include:

- trials have included predominantly elderly high-risk patients
- sinus rhythm is difficult to achieve (39–63%)
- rate control strategies can result in sinus rhythm in up to 35% of patients
- underlying heart disease that initiates the AF persists
- there may be antiarrhythmic drug side-effects
- anticoagulation is still required even if rhythm control is successful.

However, rhythm control (if possible) appears superior in patients with LV dysfunction, with both amiodarone and dofetilide reducing mortality when sinus rhythm is achieved.[43,44] The paucity of data in younger patients (less than 60 years) favours initial attempts at rhythm control, particularly in those with structurally normal hearts, in the hope that progressive atrial electrical and anatomical remodelling is prevented.

RECENT ONSET OR PAROXYSMAL AF

*VENTRICULAR RATE CONTROL (**TABLE 22.6**)*

The urgency of ventricular rate control depends on the clinical situation and spontaneous reversion of AF is common. Treatment may not be necessary, and a reasonable strategy is based on clinical status:

- Haemodynamically unstable with rapid ventricular rate requires immediate synchronised DC shock (in addition to drug therapy) to control rate urgently.
- Haemodynamically stable, symptomatic with depressed LV function: semi-urgent synchronised DC shock or drug therapy, digoxin or amiodarone to control ventricular rate.
- Haemodynamically stable, symptomatic, normal LV function: control of ventricular response with beta-adrenergic blockers, diltiazem, digoxin (digoxin has poor control with exertion and other settings with increased sympathetic tone), magnesium (short-term), amiodarone or sotalol.
- Haemodynamically stable, with no structural heart disease and minimal or no symptoms: no immediate treatment is an option. Most cases will revert spontaneously within 24 hours. Single-dose flecainide for paroxymal AF has been recommended

Table 22.6 Drugs for ventricular rate control in atrial fibrillation

	ACUTE	CHRONIC
STABLE	BETA BLOCKERS Metoprolol 2.5–5 mg i.v. bolus over 2 min – up to 3 doses Esmolol 50–200 μg/kg/min i.v. *NON*-DIHYDROPYRIDINE CALCIUM CHANNEL ANTAGONISTS Verapamil 0.0375–0.15 mg/kg i.v. over 2 min	 Metoprolol ER 100–200 mg oral daily Atenolol 25–100 mg oral daily Bisoprolol 2.5–10 mg oral daily Verapamil 40 mg oral b.d. up to 360 mg ER oral daily Diltiazem 60 mg oral t.d.s. up to 360 mg ER oral daily
UNSTABLE: HYPOTENSION HEART FAILURE	Digoxin 0.5–1.0 mg i.v. Amiodarone 5 mg/kg i.v. over 1 h	Digoxin 0.125–0.50 mg oral daily Amiodarone 100–200 mg oral daily Dronedarone 400 mg oral b.d.

Table 22.7 Drugs for pharmacological conversion of recent-onset atrial fibrillation

DRUG	DOSE	FEATURES
Amiodarone	5 mg/kg i.v. over 1 h	Will slow ventricular rate Conversion delayed Amiodarone 80–90%, placebo 40–60% at 24 h Suitable structural heart disease and heart failure
Flecainide	2 mg/kg i.v. over 10 min 200–300 mg oral	Not suitable for structural heart disease or heart failure 67–92% conversion at 6 h Majority within 1 h of i.v. dose May prolong QT Risk of atrial flutter and 1 : 1 conduction
Ibutilide	1 mg i.v. over 10 min Further dose after 10 min	50% conversion within 90 min Risk of QT prolongation and torsades de points high
Propafenone	2 mg/kg i.v. over 10 min	Not suitable for structural heart disease or heart failure 41–91% conversion within 3 hours May prolong QT Risk of atrial flutter and 1 : 1 conduction
Vernakalant	3 mg/kg i.v. over 10 min Further 2 mg/kg if required	Suitable for structural heart disease and heart failure Rapid in approximately 10 min in responders 50% conversion rate 99% of responders remain in sinus rhythm at 24 h after single dose Well tolerated

(contraindicated in patients with structural heart disease).[45]

- If pre-excitation is suspected beta-adrenergic blockers, non-dihydropyridine calcium channel antagonists, digoxin and adenosine are contraindicated and amiodarone and class I drugs are indicated.

Ideal rate control can be defined as a resting heart rate of ≤80 beats/min, peak rate of ≤110 beats/min with 6-minute walk and an average of 100 beats/min.

CONVERSION TO SINUS RHYTHM

Antiarrhythmic drugs or DC shock cardioversion can be used. The likelihood of short- and long-term success depends on the clinical situation. Conversion to sinus rhythm is more important in young patients and those with heart failure. Maintenance of sinus rhythm is problematic: sinus rhythm at 1 year is 60% with amiodarone and 40% with sotalol, and associated with significant drug cardiac and extracardiac toxicities. The risk of stroke and need for antithrombotic therapy due to frequent AF recurrences, which may be asymptomatic, remain. Achieving sinus rhythm (especially greater than 60 years) is less important than previously thought.[39]

Pharmacological conversion of recent-onset AF is variously successful depending on the clinical setting and agent used (**Table 22.7**). Ibutilide, propafenone and vernakalant have rapid conversion rates, compared

Table 22.8 Drugs for long-term rhythm control in atrial fibrillation

DRUGS	DOSE	CONTRAINDICATIONS AND PRECAUTIONS	ECG CRITERIA FOR LOWERING DOSE OR DISCONTINUATION	AV NODE SLOWING OF PAROXYSMAL AF
Disopyramide	100–250 mg t.d.s.	Systolic heart failure QT-prolonging drugs	QT>500 ms	None
Flecainide Flecainide XL	100–200 mg b.d. 200 mg daily	Creatinine clearance <50 mL/min Coronary artery disease Reduced LV ejection fraction Conduction delay	QRS duration increase >25% over baseline	None
Propafenone Propafenone SR	150–300 mg t.d.s. 225–425 mg b.d.	Coronary artery disease Reduced LV ejection fraction Conduction delay Creatinine clearance <50 mL/min	QRS duration increase >25% over baseline	Slight
Sotalol	80–160 mg b.d.	LV hypertrophy Systolic heart failure Pre-existing QT prolongation Hypokalaemia Creatinine clearance <50 mL/min	QT>500 ms	Yes
Amiodarone	600 mg daily, 4 weeks, 400 mg daily, 4 weeks then 200 mg daily	QT prolonging drugs Warfarin dose adjustment	QT>500 ms	Yes
Dronedarone	400 mg b.d.	Heart failure NYHA Class III–IV QT prolonging drugs CYP3A4 inhibitors Creatinine clearance <30 mL/min	QT>500 ms	Yes

with flecainide and amiodarone the slowest. Amiodarone, ilbutilide and vernakalent are suitable in heart failure. All have risk of QT prolongation and proarrhythmia, with ibutilide being the worst and vernakalant the best, although there are anecdotal case reports of ventricular arrhythmias with the latter.[46–48]

Although long-term treatment goals increasingly favour chronic rate control (see Table 22.6), antiarrhythmic drugs are still used to promote long-term rhythm control (**Table 22.8**). All have many contraindications and precautions, with amiodarone the best from a cardiac perspective and worst from an extracardiac point of view. The dilemma of long-term antiarrhythmic treatment in AF is highlighted by the diametrically opposite effects that dronedarone has been shown to produce in this setting.[49] In ATHENA, dronedarone decreased all cause, cardiovascular and presumed arrhythmia mortality, stroke and heart failure, whereas in PALLAS all these outcomes were worse. In PALLAS all patients had 'permanent' AF and there was twice the baseline incidence of heart failure. Benefit would appear to be crucially dependent upon securing sinus rhythm, absence of structural substrate for proarrhythmia and cardiac reserve to tolerate the drug.

DC SHOCK CARDIOVERSION

DC shock cardioversion is indicated either before 24–48 hours or after appropriate anticoagulation protocol. Combining DC shock with antiarrhythmic drugs to promote maintenance of sinus rhythm is favoured; especially if risk factors for relapse exist. Cardioversion is less likely to be successful if:

- AF has been present for over 1 year
- left atrial size is greater than 45 mm
- untreated conditions are present (e.g. thyrotoxicosis, valvular heart disease and heart failure).

Critically ill patients who are septic, postoperative or on drugs such as catecholamines are likely to relapse.

ANTICOAGULATION AND CARDIOVERSION[50,51]

Loss of atrial contraction with AF is associated with stasis of blood flow and formation of blood clots in the left atrium, particularly the atrial appendage. Reversion

to sinus rhythm and return of more effective atrial contraction may cause expulsion of any atrial clots and systemic emboli. Once AF has been present for more than 48 hours – some authors stipulate 24 hours – the risk of systemic emboli is significant and anticoagulation is required prior to DC shock cardioversion. The current recommended period of anticoagulation prior to DC shock cardioversion is 3 weeks. This 3-week period can be shortened to 1 day for heparin and 5 days for warfarin if the left atrium can be demonstrated free of clot using transoesophageal echocardiography. With this accelerated approach, heparin dose should be titrated to an activated partial thromboplastin time 2–3 times control or warfarin to produce an international normalised ratio (INR) of 2.0–3.0. In many clinical situations such as recent surgery or other bleeding risks, anticoagulation is contraindicated and elective cardioversion should be delayed until recommended anticoagulation cover is safe. Following successful cardioversion to sinus rhythm the risk of systemic embolism continues as the propensity to form atrial clot remains owing to atrial contractile stunning and anticoagulation should be continued for 4–6 weeks.

ATRIAL FIBRILLATION ABLATION THERAPY

Ablation techniques for AF have been continuously refined since the original Maze III surgical procedure, which involved numerous atrial incisions to form a maze-like pattern of scarring, blocking propagation of arrhythmia. The utility of this procedure was limited because it was surgical, with longer bypass times, postoperative bleeding and impaired atrial contractility. The magnitude of this original procedure was based on the belief that the entire atrium was involved in the initiation and maintenance of the fibrillatory conduction. This may be true for long-standing AF but paroxysmal AF appears to originate primarily at the junction of the left atrium and pulmonary veins. AF in 94% of patients is initiated by rapid discharges from one or more foci at or near the pulmonary vein orifices.[52] Atrial tissue in this area has heterogeneous electrophysiological properties and there is also clustering of vagal inputs, which creates substrate for rapid discharges that initiate micro-re-entrant circuits or 'rotors'. These high-frquency periodic rotors send spiral wave fronts of activation into surrounding atria. Localised ablation of a single dominant foci and rotor is inadequate as there are usually multiple foci.

There is renewed interest in surgical AF ablation therapy in conjunction with cardiac surgery. Complications have been reduced with energy (cryotherapy, radiofrequency) rather than incisions and the extent of lesions reduced. The minimum lesion set is now considered to be encirclement of pulmonary veins, linear lesion from the inferior pulmonary vein to mitral annulus and from the coronary sinus to the inferior vena cava.

Left atrial catheter (transatrial septum) AF ablation isolating all four pulmonary veins using radiofrquency is being heralded as the possible AF cure. Results are improving as all pulmonary veins are now isolated and the encircling lesion is clear of the pulmonary vein antrum (reducing pulmonary vein stenosis). Success rates of 81% (75–88%) free of AF and off drugs are reported. Success appears long term as any recurrence occurs early. A further 10–20% may become responsive to antiarrhythmic drugs which were previously ineffective. Repeating the procedure can increase success to >90% with failure only in patients found to have extensive atrial scarring (predicting and excluding patients with this extensive atrial scarring is a major future challenge). Although not yet the universal cure, the results are two- to threefold better than antiarrhythmic drugs alone.

Complication rates are also falling associated with:

- intracardiac echocardiography ensuring safer transeptal puncture and positioning of isolating lesions clear of the pulmonary vein antra
- higher levels of procedural anticoagulation
- strict limitations on radiofrequency energy output.

Transient ischaemic attacks, strokes, tamponade/perforation and symptomatic pulmonary vein stenosis are all well below 1% respectively. Proarrhythmia resulting from re-entrant tachycardia from incomplete ablative lesions is more common. Some are advocating ablation as first-line treatment whereas most are selecting younger patients (less than 70 years) with paroxysmal AF for whom antiarrhythmic therapy has failed, left atrial diameter is less than 5 cm and ejection fraction is greater than 40%.[27] Head-to-head studies comparing ablation and antiarrhythmic drugs are appearing with suggested survival benefit, improved quality of life, reduced adverse effects and cost-effectiveness after approximately 3 years with catheter AF ablation therapy.[53,54]

ANTICOAGULATION FOR CHRONIC ATRIAL FIBRILLATION[35]

VALVULAR ATRIAL FIBRILLATION

A 17-fold increased risk of embolic stroke with rheumatic mitral valve disease requires warfarin (INR 2–3). With prosthetic valves there is a similar target range of INR, though the exact level is dependent on the type of valve.

NON-VALVULAR ATRIAL FIBRILLATION

The risk of stroke has been determined by the $CHADS_2$ score (assign 1 point for congestive heart failure, hypertension, age=75 years and diabetes mellitus, and 2 points for stroke/TIA).[55] The $CHADS_2$ score has been further developed to the CHA_2DS_2VASc score to improve risk stratification of patients at moderate risk by doubling points to 2 for age ≥75 and including

Table 22.9 CHA_2DS_2VASc score and stroke risk stratification

	$CHA_2DS_2VAS_C$ SCORE	
RISK FACTOR		*SCORE*
Congestive heart failure LV dysfunction ejection fraction ≤ 40%	C	1
Hypertension	H	1
Age ≥ 75	A_2	2
Diabetes mellitus	D	1
Previous stroke, TIA or systemic embolism	S_2	2
Vascular disease – myocardial infarction, complex aortic plaque, prior peripheral revascularisation, amputation or angiographic evidence	V	1
Age 65–74	A	1

vascular disease (prior myocardial infarction, peripheral artery disease determined by prior revascularisation, amputation or angiographic evidence and aortic plaque, age 65–74 and female sex) (**Table 22.9**).

The treatment options are discussed below.

WARFARIN

Adjusted-dose warfarin reduces relative risk of stroke by 62%. The absolute risk reduction is 2.8% per year for primary and 8.4% per year for secondary prevention, although intracranial haemorrhage occurs (0.3% per year). Low-dose warfarin (INR 1.5–2.0) is less effective than an INR of 2.0–3.0 but has fewer haemorrhagic complications. Embolic stroke rate doubles as INR falls from 2.0 to 1.7, and is markedly higher at an INR of 1.3 compared with 2.0.[50,57]

ASPIRIN

Aspirin has reduced efficacy when compared with warfarin, with a 22% relative risk reduction and an absolute risk reduction of 1.5% and 2.5% per year for primary and secondary prevention. Warfarin compared with aspirin for AF will prevent 23 strokes and result in nine additional major bleeds per 1000 patients per year.

CLOPIDOGRIL PLUS ASPIRIN

Although warfarin is better under ideal circumstances, poor INR control will readily erode this benefit.

WARFARIN COMBINED WITH ANTIPLATELET THERAPY

There is no benefit over warfarin alone.

DABIGATRAN ETEXILATE

This direct thrombin inhibitor is a new anticoagulant that is likely to have an increasing role in AF anticoagulation with the benefit of fixed dosing not requiring monitoring. In non-valvular AF, dabigatran 150 mg b.d. had a 35% reduction in stroke and systemic embolism compared with warfarin. There was a similar rate of major bleeding, although intracranial haemorrhage was reduced by 59%. The lower dose of 110 mg b.d. had similar embolic efficacy to warfarin but with reduced bleeding. Dabigatran clearance is importantly influenced by creatinine clearance of less than 50 mL/min and rapid reversal is problematic.

RECOMMENDATIONS FOR ANTICOAGULATION IN PATIENTS WITH ATRIAL FIBRILLATION

Non-valvular AF

INR adjusted warfarin (2.0–3.0 target 2.5) or aspirin according to CHA_2DS_2VASc score and HAS-BLED score (**Tables 22.10** and **22.11**).

Dabigatran may be substituted for warfarin, depending on risk of bleeding. Risk of bleeding can be determined by the HAS-BLED score. With a HAS-BLED score of 0–2, dabigatran 150 mg bd gives superior embolic prevention with reduced intracranial haemorrhage. With a HAS-BLED score of ≥3, 110 mg b.d. gives similar efficacy to warfarin, but reduced haemorrhagic complications.

Valvular AF

Warfarin is indicated. Direct thrombin inhibitors are yet to be studied in this situation.

Risk of haemorrhage is reduced by keeping INR=3, systolic blood pressure <135 mmHg (17.95 kPa) and avoiding antiplatelet drugs.

Table 22.10 Approach to thromboprophylaxis in patients with atrial fibrillation.

CHA_2DS_2VASC SCORE	RECOMMENDED ANTITHROMBOTIC THERAPY
≥2	Oral anticoagulation – warfarin INR 2.0–3.0 Target 2.5 – dabigatran – HAS-BLED score 0–2: dabigatran 150 mg b.d. <2: dabigatran 110 mg b.d.
1	Either oral anticoagular – warfarin INR 2.0–3.0 Target 2.5 – dabigatran 110 mg b.d., *or* – aspirin 75–325 mg daily Prefer oral anticoagulation rather than aspirin
0	Either aspirin 75–325 mg daily, *or* No antithrombotic therapy Prefer no antithrombotic therapy rather than aspirin

Table 22.11 HAS-BLED bleeding risk score

H	Hypertension – systolic >160 mmHg (21.3 kPa)	1
A	Abnormal renal or liver function (1 point each) – chronic dialysis, renal transplant or creatinine ≥200 μmol/L – cirrhosis, bilirubin >2×upper limit of normal or liver enzymes >3×upper limit of normal	1 or 2
S	Stroke	1
B	Bleeding – previous history of bleeding, abnormal coagulation or anaemia	1
L	Labile INRs Unstable or high INRs, poor time in therapeutic range <60%	1
E	Elderly >65 years	1
D	Drugs or alcohol – antiplatelet agents, non-steroid anti-inflammatory drugs – alcohol abuse	1 or 2
	Maximum score	9

Temporary cessation of anticoagulation for AF with surgery is a common problem. Valvular AF requires heparin or enoxiparin until surgery and recommencement of heparin/enoxiparin, then warfarin as soon as safely possible. Non-valvular CHA_2DS_2VASc score <2 can have anticoagulation withheld with minimal risk. Non-valvular CHA_2DS_2VASc score of ≥2 is increasingly managed as valvular AF.

Angioplasty and stenting of coronary arteries require aspirin and clopidogrel to maintain stent patency. Stenting in patients already on warfarin for AF is a common problem.

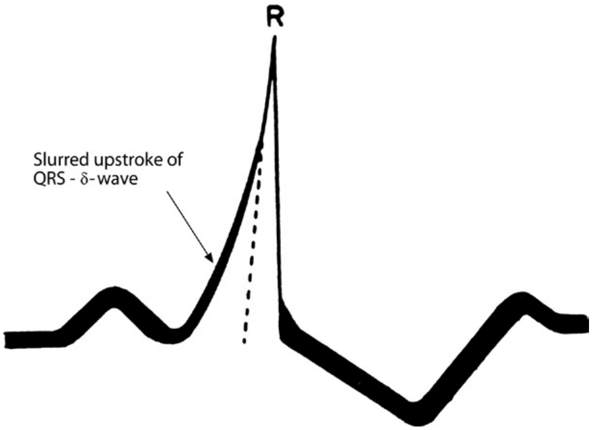

Figure 22.25 Ventricular pre-excitation via accessory pathway giving rise to a slurred upstroke and widened QRS complex.

RECOMMENDATIONS FOR AF PATIENTS REQUIRING CORONARY ARTERY STENTING

- Non-valvular CHA_2DS_2VASc score <2: cease warfarin as aspirin and clopidorel are started.
- Valvular AF and non-valvular with CHA_2DS_2VASc score ≥2: add aspirin and clopidogrel to continued warfarin treatment.

PRE-EXCITATION SYNDROME

Pre-excitation syndromes have an additional or accessory AV pathway. The term 'WPW syndrome' is usually applied when tachyarrhythmia is present.

ECG

During sinus rhythm, an atrial impulse will reach the ventricles via both the AV node and the accessory AV pathway. The latter conducts the atrial impulse to the ventricles before the AV node, resulting in ventricular pre-excitation and a short PR interval. On reaching the ventricles, the pre-excitation impulse is not conducted via the specialised conducting system. Hence, early ventricular activation will be slowed, resulting in a slurred upstroke of the QRS complex, the so-called delta (δ) wave (**Fig. 22.25**). The abnormal ventricular activation also gives rise to secondary S-T segment and T-wave abnormalities. δ-wave polarity in a 12-lead ECG may help localise the anatomical position of the accessory pathway. Type A WPW is characterised by upright QRS deflections in the right precordial leads

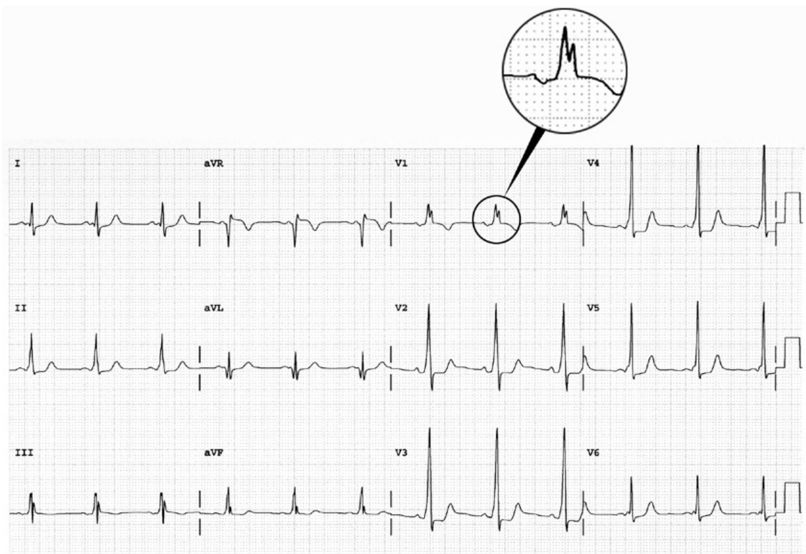

Figure 22.26 Type A Wolff–Parkinson–White syndrome with positive R-waves in the right precordial leads, short PR interval and δ-wave giving rise to a wide QRS complex.

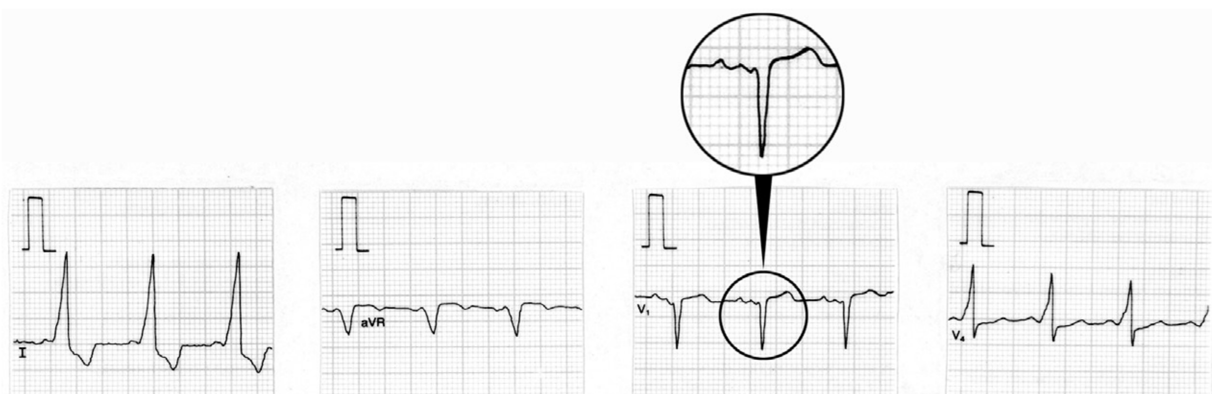

Figure 22.27 Type B Wolff–Parkinson–White syndrome with a negative QRS deflection in V_1.

(tall R-waves in V_1 and V_2) (**Fig. 22.26**). In type A WPW the accessory pathway is usually situated on the left with pre-excitation of the left ventricle. Type B WPW has a dominantly negative QRS complex in V_1 and the accessory pathway tends to be on the right with pre-excitation of the right ventricle (**Fig. 22.27**).

CLINICAL

AVRT or AF can occur with WPW. During AVRT, the re-entry impulse usually travels down the AV node and back up the accessory pathway. Ventricular activation is via the normal conducting pathways and the QRS will be narrow. Occasionally, the re-entry impulse may pass in the opposite direction (down the accessory pathway and up the AV node), resulting in a wide QRS-complex tachycardia due to abnormal slow ventricular activation. Treatment is the same as for AVRT (i.e. i.v. adenosine). AF is uncommon in WPW, but may be life-threatening. Most impulses are conducted via the accessory pathway, leading to wide QRS complexes. The ECG of WPW with AF usually shows rapid, irregular QRS complexes with variable QRS width (**Fig. 22.28**).

Ventricular response is very rapid, leading to hypotension or cardiogenic shock. This arrhythmia may degenerate to VF.

TREATMENT[23]

Treatment usually involves synchronised DC shock. Antiarrhythmic drugs may be used when patients are haemodynamically stable and the ventricular rate is not excessively rapid.

- Drugs that prolong the refractory period of the accessory pathway are useful (e.g. sotalol, amiodarone, flecainide and procainamide).
- Drugs that shorten the refractory period (e.g. digoxin) are contraindicated as they may accelerate ventricular rate.

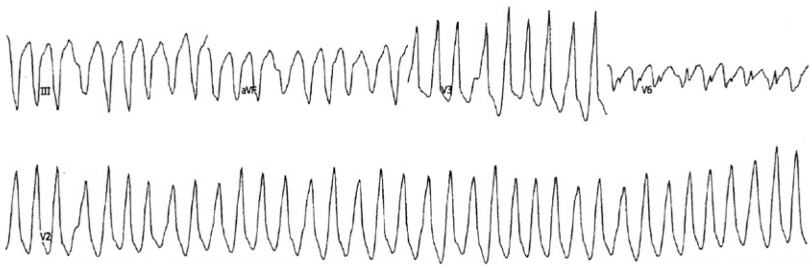

Figure 22.28 Wolff–Parkinson–White syndrome with atrial fibrillation. Rapid rate and irregularity of the broad QRS complexes help to distinguish from ventricular tachycardia.

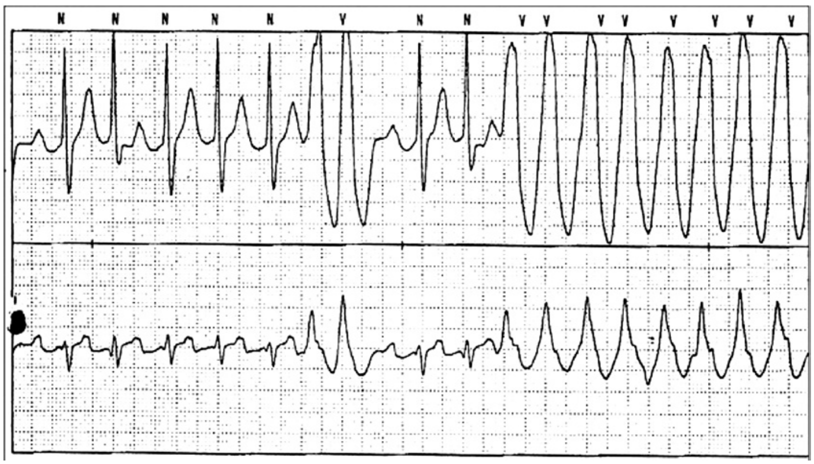

Figure 22.29 Monomorphic ventricular tachycardia preceded by a ventricular couplet.

- Verapamil and lidocaine may increase the ventricular rate during AF, and are also best avoided.[28]
- Beta-adrenergic blockers have no effect on the refractory period of the accessory pathway.

Long-term management by radiofrequency ablation of the accessory pathway is effective in selected patients.[23]

VENTRICULAR TACHYCARDIA

VT is defined as three or more VEBs at a rate greater than 130 beats/min, and may exceed 300 beats/min. VT lasting over 30 seconds is considered to be sustained. Non-sustained VT may not cause symptoms, but is associated with increased mortality in certain patients (e.g. after myocardial infarction). VT may be monomorphic (i.e. the same QRS morphology) (**Fig. 22.29**) or polymorphic (varying QRS morphology).

MONOMORPHIC VENTRICULAR TACHYCARDIA

This is the most common form of VT. It is commonly associated with previous myocardial infarction, and often causes symptoms (e.g. palpitations, shortness of breath, chest pain or syncope). It may result in cardiac arrest, due to the tachycardia itself or degeneration into VF. The most common mechanism is re-entry secondary to inhomogeneous activation of the myocardium and slow conduction through scar tissue from a previous myocardial infarction. AV dissociation (i.e. independent atrial and ventricular activity) (**Fig. 22.30**) is present in about 75% of instances, whereas retrograde ventricle to atrial conduction occurs in about 25%. AV dissociation is virtually diagnostic for VT during a wide-complex tachycardia, but ECG recognition of independent (and slower) atrial activity can be difficult (**Fig. 22.31**). VT is the most common cause of a wide-complex tachycardia (QRS>120 ms) and any such tachycardia should be considered VT until proven otherwise. Mistakes in diagnosis are common: SVT with aberrant conduction is often mistaken for VT. Inappropriate treatment based on incorrect diagnosis can have disastrous consequences.

ECG

Older criteria (e.g. QRS>140 ms and extreme electrical axis changes) are unhelpful in rhythm diagnosis.[58] ECG criteria initially proposed by Wellens and revised by Brugada et al permit accurate diagnosis in four sequential steps (**Fig. 22.32**).[59–61]

The sensitivity of these four consecutive steps was 0.987, with a specificity of 0.965.

- *Step 1:* is a RS complex present in any precordial lead? (QR, QRS, QS, monophasic R and rSR are not considered RS complexes.) If not (**Fig. 22.33**), the diagnosis is VT.
- *Step 2:* if a RS is present, then measure the duration of the R-to-S nadir (lowest part of the S-wave). If this

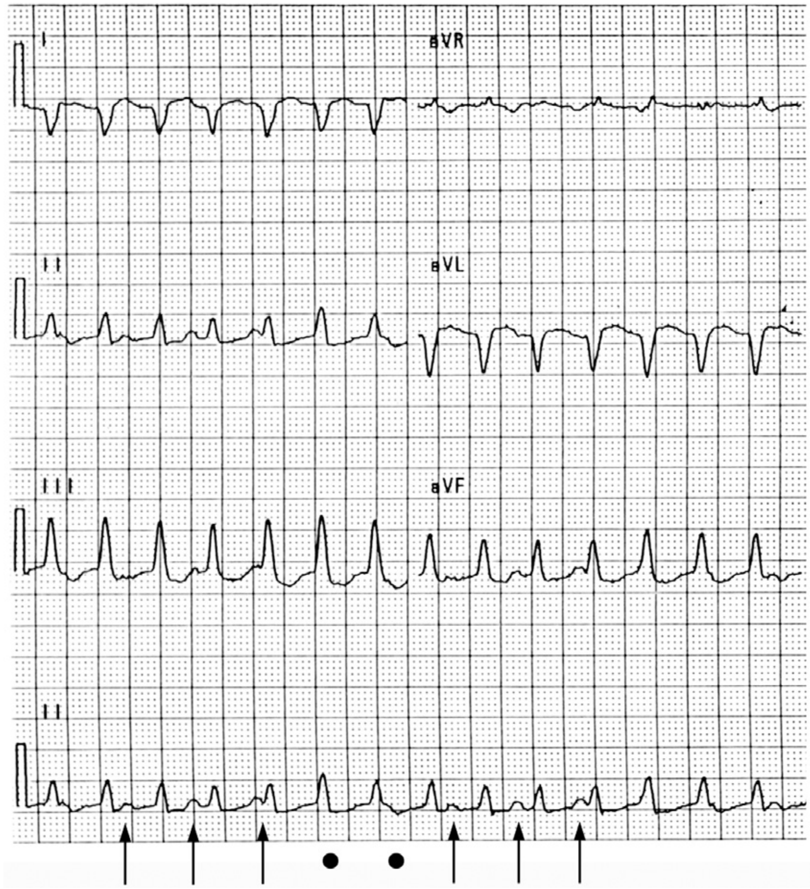

Figure 22.30 Ventricular tachycardia with obvious arteriovenous dissociation and independent P-waves are highlighted with arrows in lead II.

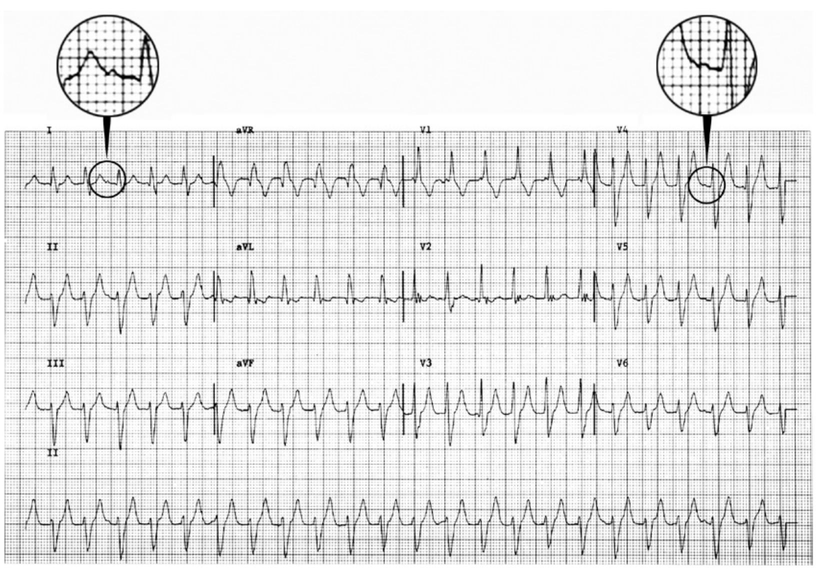

Figure 22.31 Ventricular tachycardia. Independent atrial activity can be difficult to see. Dissociated P-waves can just be seen in leads I and V_4.

1. Absent RS complex in all V leads → VT
2. R to S nadir >100ms in any V lead → VT
3. Atrio-ventricular dissociation → VT
4. Typical/classical BBB pattern → No → VT

↓

Yes

↓

SVT

Figure 22.32 Algorithm proposed by Brugada et al[59] to diagnose ventricular tachycardia in the setting of a broad QRS-complex tachycardia.

duration is >100 ms in any V lead (**Fig. 22.34**), the rhythm is VT.

- *Step 3:* if RS<100 ms, then AV dissociation is searched for (more QRS complexes than P-waves; see Figs 22.30 and 22.31). Indirect evidence of AV dissociation such as capture or fusion beats may be present. Capture beats occur when atrial sinus impulses reach the AV node when it is no longer refractory from retrograde conduction of ventricular discharges: the AV node and ventricle are then 'captured' by the sinus impulse. The resultant QRS will occur earlier than the next expected VT complex and the QRS morphology will be that of the 'normal' underlying complexes for that patient. Similarly, a sinus impulse can penetrate the AV and 'fuse' with an already depolarising ventricle from the ectopic focus initiating the VT. The resulting QRS morphology of a fusion beat will be variable and depend on the relative contribution of the supraventricular and

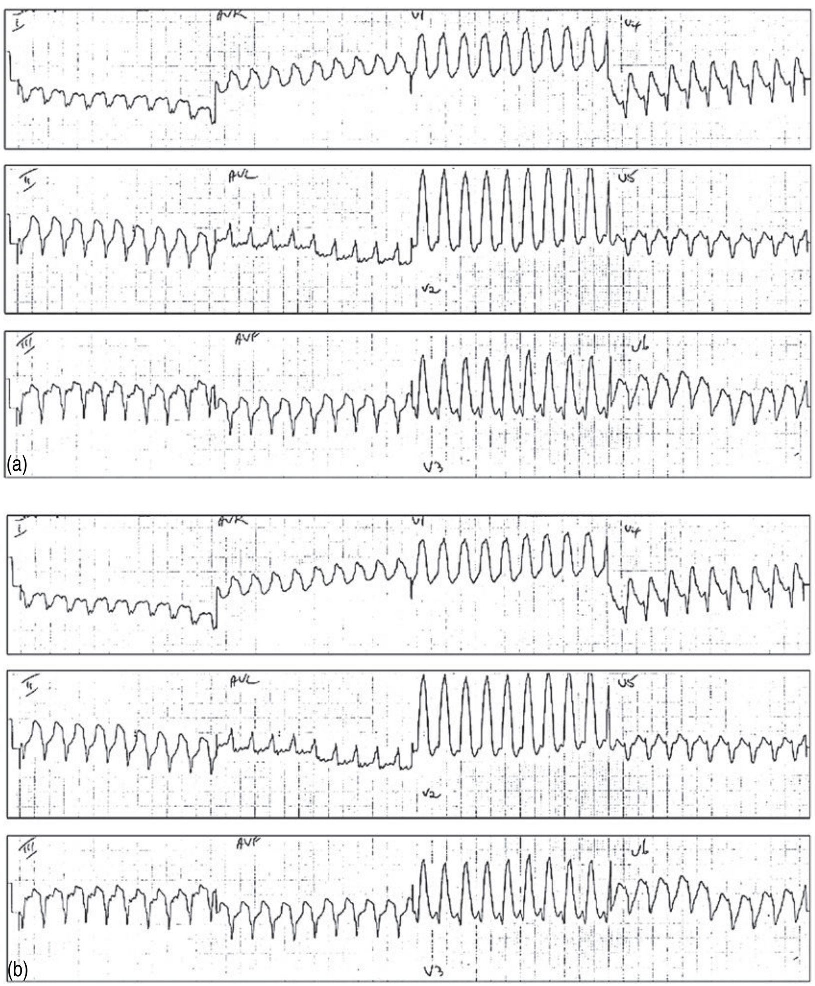

Figure 22.33 (a, b) Ventricular tachycardia. Broad QRS-complex tachycardia with absence of RS complex in all precordial leads.

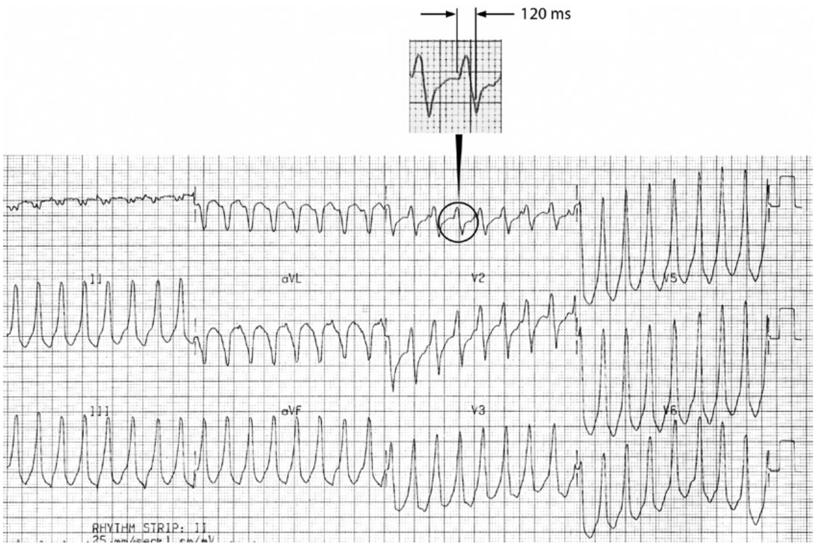

Figure 22.34 Ventricular tachycardia. Time duration of R to the nadir of the negative S-wave is 120 ms. Note also independent P-waves in lead V_1.

ventricular impulses to ventricular activation. Even a single capture or fusion beat confirms AV dissociation and VT (**Fig. 22.35**).

- *Step 4:* if AV dissociation is not present, then decide whether the wide QRS has a right or left BBB pattern. If the BBB is typical in both V_1 and V_6 leads, the rhythm is supraventricular in origin (see the section on BBB, below). If there are any atypical features, the rhythm is considered to be VT (see Figs 22.39 and 22.40, below).

Termination of a wide-complex tachycardia by i.v. adenosine strongly suggests the arrhythmia as SVT. However, adenosine in this setting has the risk of destabilising VT when blood pressure is barely compensated by vasodilatation or acceleration of accessory pathway conduction, and is not recommended by International Liaison Committee on Resuscitation (ILCOR) as a diagnostic strategy in wide-complex tachycardia.[23] Demonstration of AV dissociation by intracardiac ECG from a central venous catheter or a transvenous pacing lead signifies VT.

CLINICAL

The major cause of VT is significant coronary artery disease. Other causes include cardiomyopathy, myocarditis and valvular heart disease. Symptoms will depend on the ventricular rate, duration of tachycardia and underlying cardiac function. There are not necessarily any haemodynamic differences between VT and SVT with aberrant conduction but haemodynamic instability mandates management as for VT.

TREATMENT[23,62]

DC shock is indicated if a patient is haemodynamically unstable. Antiarrhythmic drug trial is indicated in haemodynamically stable VT.

- Amiodarone may terminate VT; there is less negative inotropic action but delayed effect.
- Sotalol and procainamide are more effective than lidocaine but are associated with significant myocardial depression.
- Although traditionally indicated, there are now doubts about the efficacy of lidocaine.

If drugs are ineffective, synchronised DC shock is indicated. Rapid right ventricular pacing may also be effective.

Long-term prevention of VT and sudden death is difficult. Sotalol guided by Holter ECG or electrophysiological testing, and empirical (i.e. non-guided) amiodarone are superior to other drugs in preventing arrhythmia recurrences. Empirical beta-adrenergic blockers also have a role. Implantable defibrillators can recognise and automatically terminate VT by rapid ventricular pacing or, if this fails, by internal DC cardioversion, which may be life-saving.

POLYMORPHIC VENTRICULAR TACHYCARDIA AND TORSADE DE POINTES

This arrhythmia has QRS complexes at 200 beats/min or greater, which change in amplitude and axis so that they appear to twist around the baseline (**Fig. 22.36**). Torsade de pointes usually has prolonged QT during sinus rhythm, and U-waves are often present (see section on long-QT syndrome, below). However, polymorphic VT may be associated with a normal QT interval in settings such as myocardial ischaemia, infarction or post cardiac surgery.

TREATMENT

Polymorphic VT associated with a normal QT interval during sinus rhythm (e.g. following AMI) should be

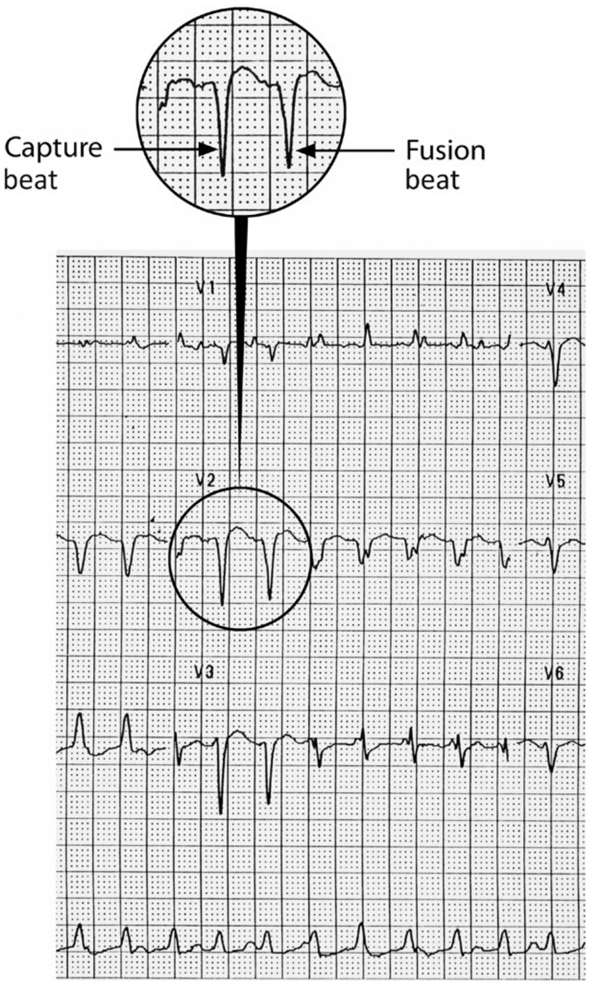

Figure 22.35 Ventricular tachycardia with a highlighted premature capture beat followed by a fusion beat showing transitional QRS morphology between the underlying normal QRS and VT complex. Note also independent P-waves.

treated in the same way as monomorphic VT. (See section on treatment of long-QT and polymorphic VT, below.)

ACCELERATED IDIOVENTRICULAR RHYTHM (AIVR)

This is often inappropriately called slow VT. Increased automaticity is probably the mechanism responsible for this relatively benign arrhythmia.

ECG

There is a wide QRS with a rate of 60–110 beats/min (**Fig. 22.37**). Sinus rate is often only slightly slower than the arrhythmia, so the dominant rhythm may be intermittent AIVR and sinus rhythm. Fusion beats are therefore common.

CLINICAL

The rhythm is commonly encountered in inferior myocardial infarction. AIVR may be misdiagnosed as VT. Occasionally, AIVR causes haemodynamic deterioration, usually due to loss of atrial systole. Increasing the atrial rate with either atropine or atrial pacing may then be necessary.

VENTRICULAR FIBRILLATION

VF always causes haemodynamic collapse, loss of consciousness and death if not immediately treated. Of patients resuscitated from VF, 20–30% have sustained an AMI, and 75% have coronary artery disease. VF (and VT) unassociated with AMI is likely to be recurrent; 50% die within 3 years.

ECG

The ECG shows irregular waves of varying morphology and amplitude (**Fig. 22.38**).

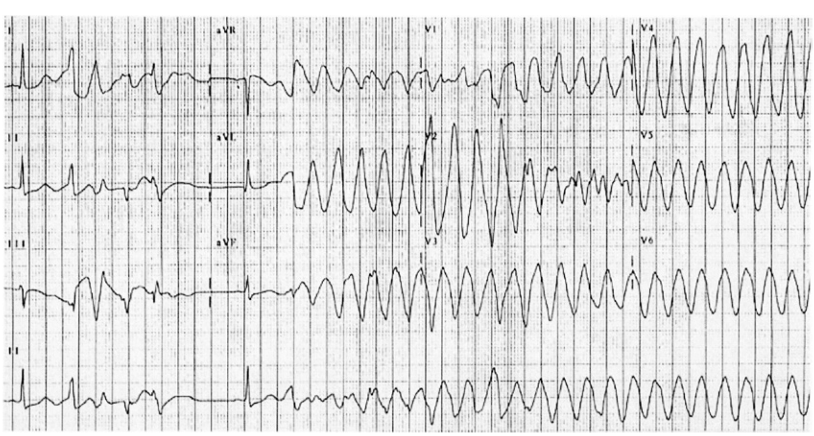

Figure 22.36 Torsade de pointes preceded by multifocal ventricular ectopic beats.

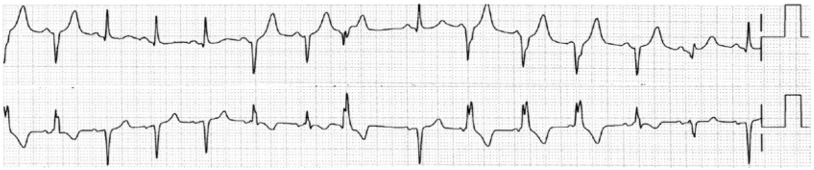

Figure 22.37 Sinus rhythm with short runs of accelerated idioventricular rhythm. Note frequent fusion beats as sinus rate is similar to the accelerated idioventricular rate.

Figure 22.38 Ventricular fibrillation with waves of varying morphology and amplitude.

CLINICAL

VF is usually associated with ischaemic heart disease, although other causes include cardiomyopathy, antiarrhythmic drugs, severe hypoxia and non-synchronised DC cardioversion.

TREATMENT[62]

Give an immediate non-synchronised DC shock at 200 J and, if ineffective, repeated at 200–360 and 360 J (or biphasic equivalent). Time should not be wasted with basic life support if immediate defibrillation can be delivered.

If DC shock sequence fails, basic and advanced life support aiming to maximise coronary blood flow with chest compressions and vasopressors is crucial to cardiac success. Until recently, any role of antiarrhythmic drugs in DC shock-resistant VF has been traditional rather than proven. Recommendations have varied from lidocaine and bretyllium to amiodarone. The ILCOR currently recommends consideration of a range of antiarrhythmic drugs, including amiodarone, lidocaine, magnesium and procainamide. Recent studies indicate amiodarone as the drug of choice for DC shock-resistant VF. Amiodarone (300 mg) was superior to lidocaine and, in another study, 5 mg/kg followed by 2.5 mg/kg if required was superior to lidocaine. There is an incidence of bradycardia and hypotension but no difference in adverse effect profile between lidocaine and this sizeable amiodarone dose.[63,64] After return of circulation, appropriate antiarrhythmic therapy is less clear but the role of lidocaine continues to disappear. Precipitating factors should be sought and treated (for long-term management issues, see the section on sudden cardiac death, below).

RIGHT BUNDLE BRANCH BLOCK (FIG. 22.39)

In right BBB (RBBB) the normal rapid coordinated depolarisation of the right ventricle is lost due to conduction block in the right branch of the bundle of His. There is normal rapid depolarisation of the septum and the initial deflection of the QRS is not altered. The activation of the free wall of the left ventricle is also normal. However the final activation of the free wall of the right ventricle is slow and anomalous, leading to a broad QRS.

ECG

The ECG shows wide QRS (>120 ms) and the QRS morphology in the right ventricular leads V_1 and V_2 is often M shaped. This results in two R-waves, with the smaller of the R-waves being designated 'r' and the larger 'R'. The classical pattern is the M-shaped rSR in V_1 or V_2 and a broad S-wave in LV leads, especially I and V_6. In V_1 the R-wave is greater in amplitude than the R-wave. In V_6 the R-wave is greater than any S-wave present. Partial RBBB is identical, except the QRS duration is 110–120 ms.

CLINICAL

RBBB may be a normal variant, but may occur with massive pulmonary embolism, right ventricular hypertrophy, ischaemic heart disease and congenital heart disease (note that myocardial infarction can be diagnosed in the presence of RBBB).

LEFT BUNDLE BRANCH BLOCK (FIG. 22.40)

In left BBB (LBBB), there is delayed and anomalous activation of the interventricular septum from right to left (i.e. in the opposite direction to normal) and the free wall of the left ventricle.

ECG

There is a wide QRS (>120 ms) and in V_1 the characteristic morphology shows an rS or QS. In V_6 there are primary and secondary R-waves (RR′), often resulting in M-shaped or plateau morphology. Q-waves are never seen in LV leads (V_4–V_6) (note that myocardial infarction cannot usually be diagnosed in the presence of LBBB). Partial LBBB is similar, except that the QRS duration is 110–120 ms.

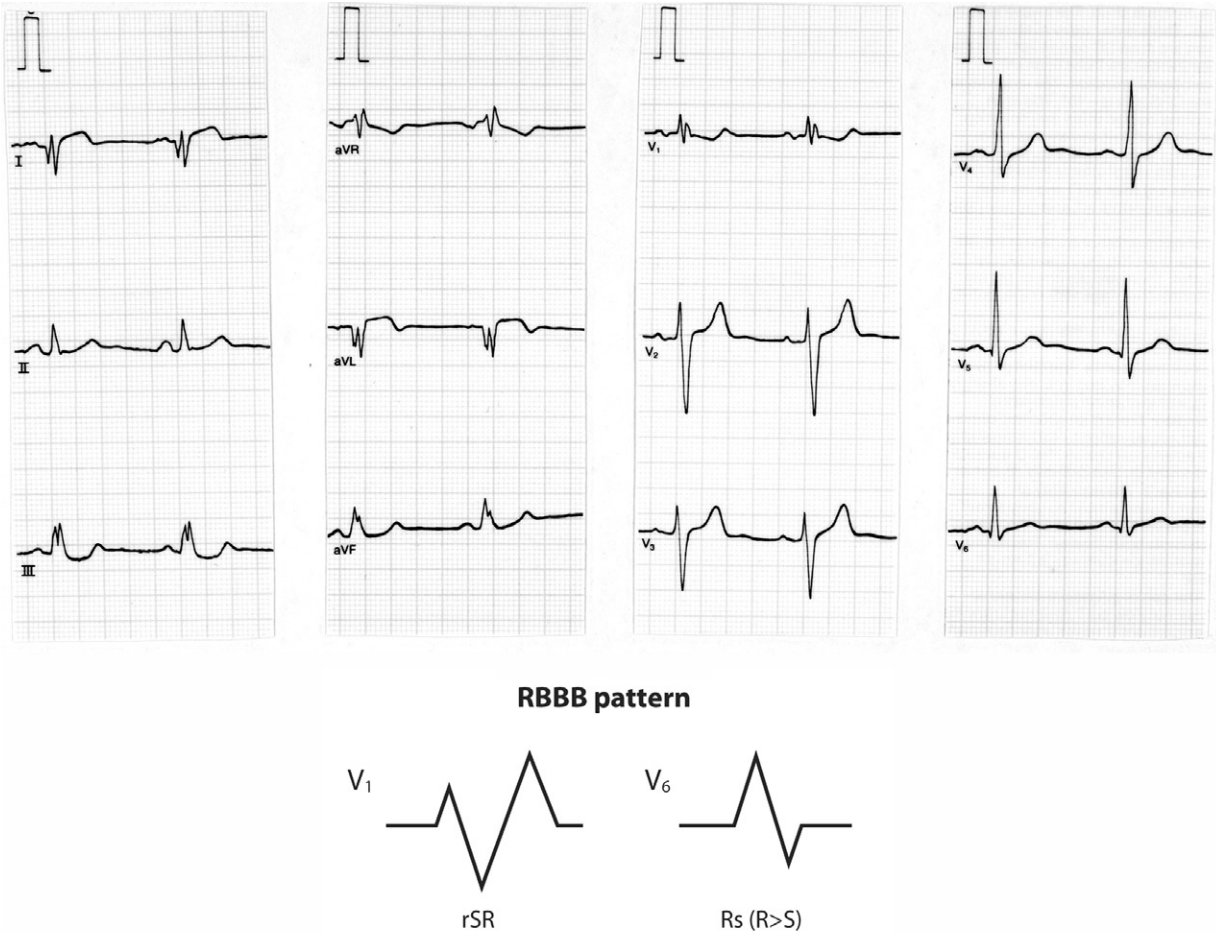

Figure 22.39 Right bundle branch block (RBBB) with characteristic M-shaped rSR complex in lead V_1 and Rs complex in V_6.

CLINICAL

LBBB is often associated with heart disease such as coronary artery disease, cardiomyopathy or LV hypertrophy. LBBB makes diagnosis of myocardial infarction difficult and the development of a new LBBB fulfils ECG criteria of acute infarction.

HEMIBLOCKS

The left branch of the bundle of His divides into the left anterosuperior division supplying the anterior superior lateral wall of the left ventricle and the posteroinferior division supplying the posterior inferior diaphragmatic surface of the left ventricle. Although block can occur in either division it is more common in the anterosuperior division, as it is more vulnerable to disease processes due to its longer course and thinner dimension. The anterosuperior division runs close to the aortic valve and tends to be involved in degenerative processes affecting this valve. The posteroinferior division is shorter and thicker and, unlike the anterosuperior division, has a double blood supply.

LEFT ANTERIOR HEMIBLOCK

There is left-axis deviation (usually lead I predominantly positive, leads II and III predominantly negative) with initial R-wave in inferior leads (II, III, aVF).

LEFT POSTERIOR HEMIBLOCK

There is usually right-axis deviation (lead I predominantly negative and lead III predominantly positive). Other causes of right-axis deviation (e.g. right ventricular hypertrophy) need to be excluded.

CLINICAL

RBBB with either left anterior hemiblock (**Fig. 22.41**) or left posterior hemiblock indicates an extensive conduction defect and a poor prognosis (high risk of complete heart block), especially in AMI.

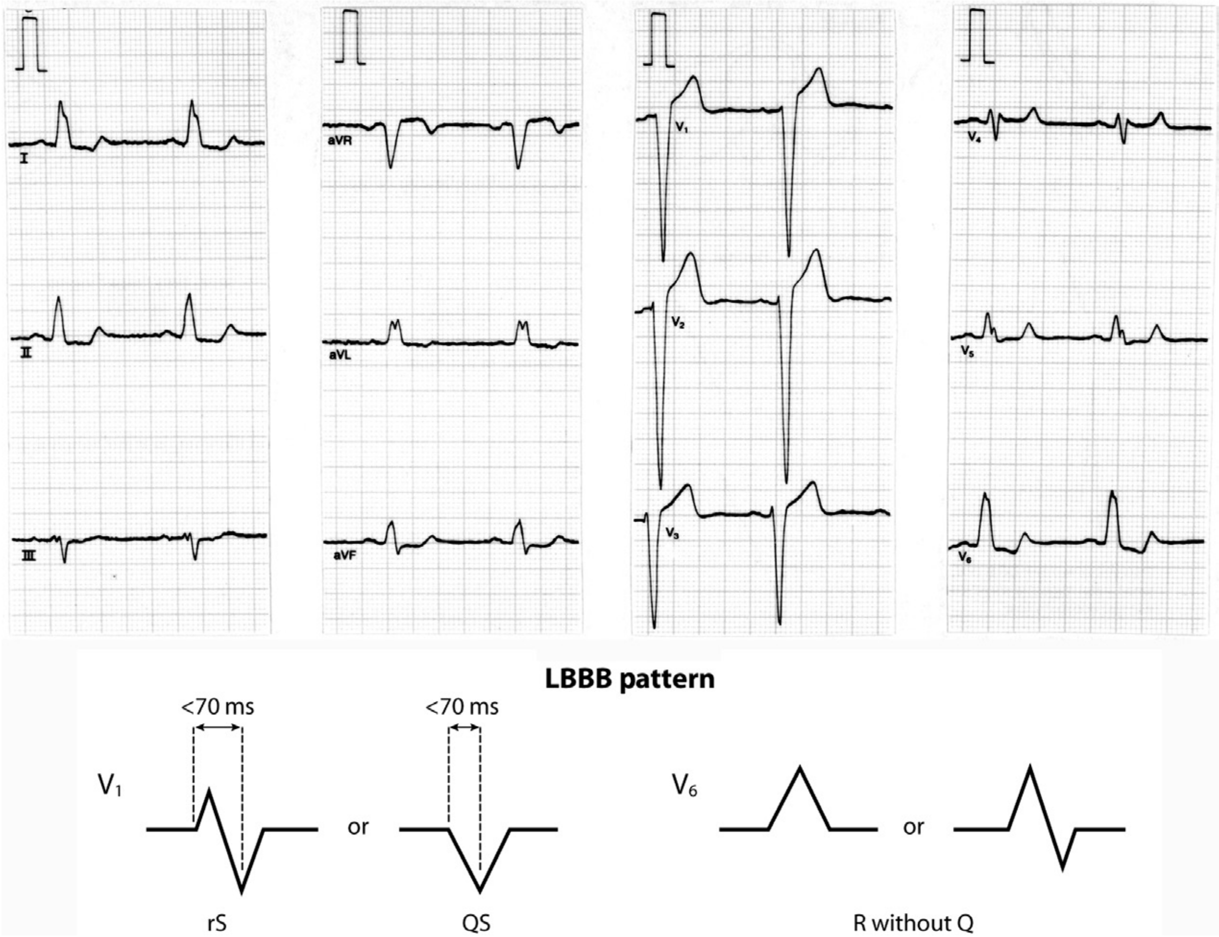

Figure 22.40 Left bundle branch block (LBBB).

HYPERKALAEMIA

A high serum K^+ can produce ECG changes (**Fig. 22.42**). Early changes consist of tall peaked T-waves with reduced P-wave amplitude. Progressive widening of the QRS may be confused with BBB. Cardiac arrest may eventually occur.

ATRIOVENTRICULAR BLOCK[62]

AV block is a delay or failure of impulse conduction from the atria to the ventricles. AV block is classified according to whether conduction of atrial impulses is delayed (first degree), blocked intermittently (second degree) or blocked completely (third degree).

FIRST-DEGREE AV BLOCK

ECG

PR interval (measured from the onset of the P-wave to the onset of the QRS) exceeds 200 ms (**Fig. 22.43**). Each P-wave is followed by a QRS. PR intervals may be prolonged to such a degree that the P-wave is buried in the previous T-wave or even QRS.

CLINICAL

First-degree AV block is commonly associated with increased vagal tone, and occasionally with drugs (especially digoxin), ischaemic heart disease (particularly inferior myocardial infarction) and rheumatic fever. It usually causes no symptoms and requires no treatment. If associated with digoxin, the drug should be ceased or the dose decreased.

SECOND-DEGREE AV BLOCK

Second-degree AV block is characterised by intermittent failure of AV conduction and is classified into Mobitz types I and II. Second-degree AV block can occur in SVTs; however, the conduction block is a physiological 'protective' mechanism in the setting of rapid atrial impulses.

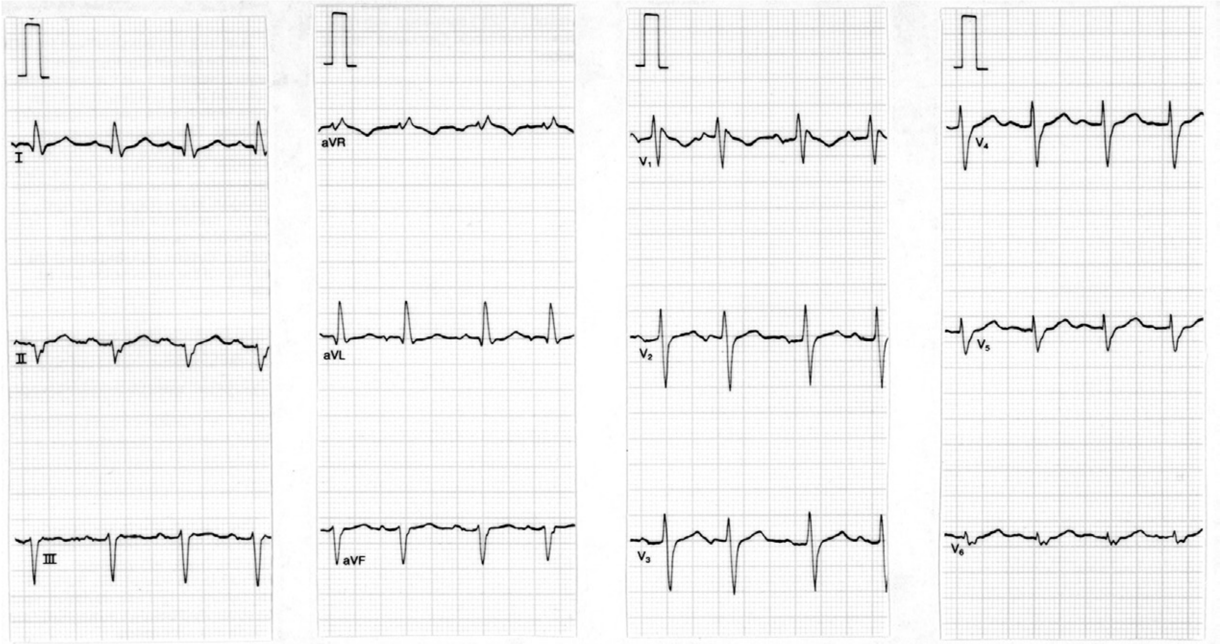

Figure 22.41 Right bundle branch block with left anterior hemiblock. There is left-axis deviation (mean frontal axis of –75°) and small R-waves in II, III and aVF.

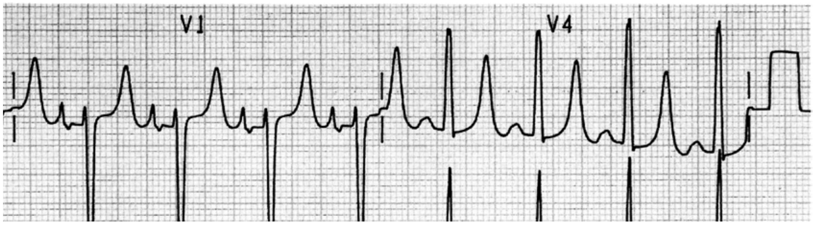

Figure 22.42 Sinus rhythm with peaked 'tent-shaped' T-waves in a patient with a serum potassium of 7.6 mmol/L.

MOBITZ TYPE I (WENCKEBACH)

Delay in AV conduction increases with each atrial impulse until an atrial impulse fails to conduct. This is usually a repetitive pattern, which may or may not begin with first-degree AV block. The level of AV block in type 1 is usually in the AV node itself and can be physiological (increased vagal tone) as well as pathological.

ECG

There is progressive lengthening of the PR interval over successive cardiac cycles, culminating in a non-conducted P-wave, resulting in a missed beat (**Fig. 22.44**). Type 1 is common in fit healthy people in the presence of high levels of resting vagal tone (**Fig. 22.45**).

CLINICAL

The condition is generally benign and does not carry the adverse likelihood of progression to complete AV block, although it may occur with inferior infarction. Treatment is rarely necessary.

MOBITZ TYPE II

There is intermittent failure of conduction of atrial impulses to the ventricles without preceding increases in the PR interval. The ratio of conducted to non-conducted atrial impulses varies; for example, every second or fourth atrial impulse may be conducted (i.e. 2:1 or 4:1 second-degree AV block). The lesion causing type II is usually situated in the bundle of His and is always pathological.

ECG

PR interval remains constant prior to the blocked P-wave. There is always a constant P–QRS-wave ratio: the P-waves are two (**Fig. 22.46**), three (rare) or four times more frequent than QRS-waves.

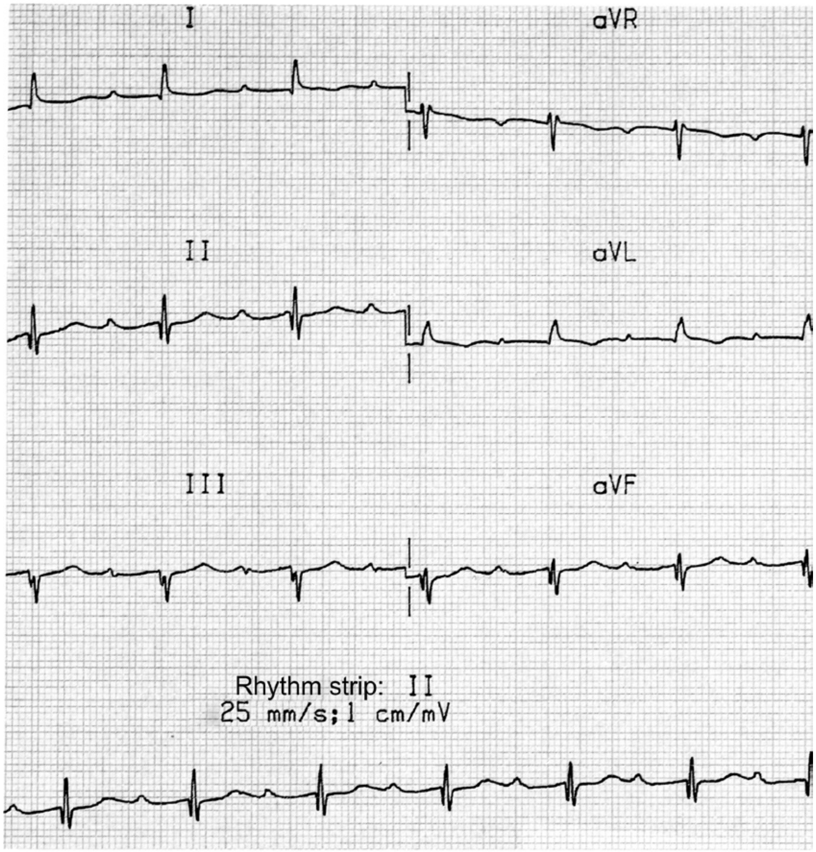

Figure 22.43 Sinus rhythm with first-degree AV block. The PR interval is 360 ms. Note inferior-wall myocardial infarction with Q-waves in II, III and aVF.

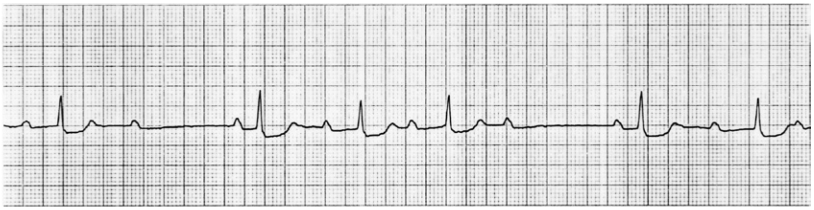

Figure 22.44 Mobitz type I (Wenckebach) second-degree arteriovenous block. Progressive lengthening of PR interval results in the failure of the second and sixth P-wave to be conducted.

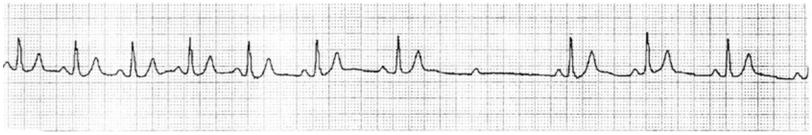

Figure 22.45 Intermittent type I second-degree arteriovenous block in a healthy male with obvious background sinus arrhythmia. Constant PR interval of 0.14 s suddenly increases to 0.22 s and next P-wave is not conducted.

Figure 22.46 Mobitz type II second-degree arteriovenous (AV) block. Persistent 2 : 1 AV block with the atrial rate at 108 beats/min and the ventricular rate 54 beats/min.

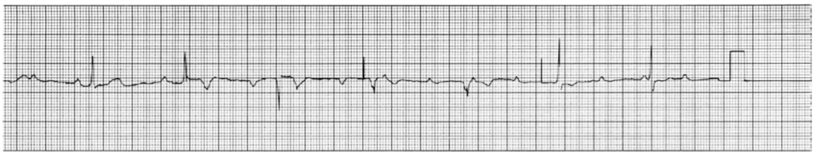

Figure 22.47 Leads I, aVR, V_1 and V_4 showing third-degree arteriovenous block. Complete dissociation of atrial activity at a rate of 107 beats/min and the ventricular rate at 46 beats/min. The escape rhythm is junctional (high up in the bundle of His) with a narrow QRS morphology.

Figure 22.48 Third-degree arteriovenous block with an atrial rhythm at 135 beats/min and a broad distal ventricular escape rhythm which is unstable at a rate of 30 beats/min.

CLINICAL

It is likely to be associated with structural heart disease. Slower symptomatic ventricular rates may require pacing. The AV block may be intermittent or persistent. The adverse prognosis relates to the frequency of progression to complete AV block.

THIRD-DEGREE (COMPLETE) AV BLOCK

This rhythm occurs when no atrial impulses are conducted to the ventricles; atrial and ventricular contractions are dissociated. The SA node usually continues to depolarise the atria, whereas ventricular activation depends on a standby escape pacemaker located below the block. The escape pacemaker may be close to the His bundle (narrow QRS, stable pacemaker usually 40–60 beats/min) (**Fig. 22.47**), or more distal in ventricular tissue (wide QRS, relatively unstable pacemaker with a rate of 20–40 beats/min) (**Fig. 22.48**). If no ectopic escape pacemaker emerges, ventricular asystole will occur, resulting in a Stokes–Adams attack, or death if the episode is prolonged. Torsade de pointes may also occur associated with the bradycardia.

ECG

The ECG shows normal regular P-waves completely dissociated from QRS complexes. The QRS rate is always significantly slower than the P-wave rate and may be very slow at times.

CLINICAL

Idiopathic fibrosis of the conduction system is the most common cause. Other causes include myocardial infarction, valvular heart disease, cardiac surgery and a congenital form of complete heart block. Cardiac pacing is usually required to increase heart rate and cardiac output. Congenital forms often have a relatively fast escape ventricular rate, and patients may remain asymptomatic for many years.

SICK-SINUS SYNDROME

This consists of a number of sinus node abnormalities, including inappropriate sinus bradycardia, SA blocks or sinus arrest. When sinus bradycardia or SA block occurs, junctional escape rhythms are common. There may also be abnormalities of AV conduction. Paroxysms of AF or Afl may alternate with episodes of bradycardia (bradycardia–tachycardia syndrome) (**Fig. 22.49**).

CLINICAL

The bradycardias associated with sick-sinus syndrome (SSS) may result in syncope or near-syncope. SSS is

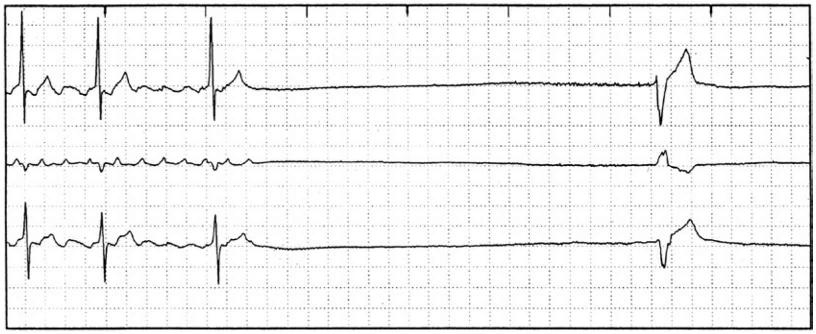

Figure 22.49 Characteristic findings in sick-sinus syndrome. Episodic atrial tachycardias (atrial flutter with variable block in this instance) with periods of sinus arrest and very slow ventricular escape rhythm upon spontaneous termination. CSM, carotid sinus massage.

often not associated with structural heart disease, but may occur with ischaemic and congenital heart disease.

TREATMENT

Cardiac pacing is usually required to control bradycardia symptoms. Atropine and low-dose isoproterenol may be useful prior to pacing, in the haemodynamically compromised patient. Bradycardia–tachycardia syndrome may require both pacing (for the bradycardia) and antiarrhythmic drugs (for the tachycardia). Anticoagulation needs to be considered if episodes of AF occur.

CRITICALLY ILL PATIENTS AND ARRHYTHMIA

In the general population of critically ill patients, excluding acute coronary syndromes and cardiac surgical patients, arrhythmia is common. The documented incidence is as high as 78%; however, the incidence of arrhythmia that requires treatment is much lower, at 15–30%. SVT is by far the most common arrhythmia that requires treatment. AF, Afl and unifocal atrial tachycardias are the most frequent, in descending order. These SVTs are rarely the cause of admission but develop early in the admission, the majority by day 2. In critically ill patients, SVTs often result in:

- adverse myocardial oxygen supply–demand balance
- compromised blood pressure, cardiac output and systemic oxygen delivery
- impaired end-organ function such as oliguria and worsening gas exchange.

The development of SVT in a critically ill patient is associated with a significant increase in mortality, especially in patients with sepsis and respiratory failure. Incidence of SVT is increased with:

- elderly patients
- evidence or past history of heart disease
- haemodynamic features of diastolic failure with elevated pulmonary artery occlusion pressure
- catecholamine infusion
- severe sepsis.

The actual dose of the catecholamine infusion does not appear to be important and, although electrolyte disturbances are common in critically ill patients, low plasma potassium and magnesium levels do not appear to be important predictors of SVT development. The incidence of SVT, particularly AF, is so high in elderly patients with heart disease on a catecholamine infusion that consideration of prophylactic strategies is worthwhile.

Risk of in-hospital stroke is increased in critically ill patients with new-onset AF, odds ratio 2.70 and greater focus on the need for embolic prophylaxis is needed.[66]

TREATMENT OF SUPRAVENTRICULAR TACHYCARDIA IN CRITICALLY ILL PATIENTS

Continuing arrhythmogenic and chronotropic factors make rate control difficult.

- Digoxin often results in poor rate control due to persisting endogenous and exogenous sympathomimetic tone. The inotropic and vasopressor effects of acute digitalisation are beneficial. Digoxin (10 μg/kg) has been shown to provide superior circulatory support to dopamine at 8 μg/kg per min in septic patients.[67]
- Irrespective of plasma levels, magnesium has been shown to be effective at rate control; however, hypotension due to vasodilatation can be seen.
- Amiodarone is particularly effective and has allowed reliable acute rate control over a period of days in critically ill patients with circulatory shock requiring catecholamine infusions.[68] It can cause hypotension if patients are rapidly loaded. In another study, magnesium was at least as effective as amiodarone in rate control and time to reversion to sinus rhythm.[69]
- Other agents, such as diltiazem, sotalol and procainamide, are associated with prohibitive myocardial depression and hypotension.

Urgent cardioversion is indicated in unstable patients. The likelihood of remaining in sinus rhythm in the setting of high endogenous and exogenous sympathomimetic tone is low without concomitant use of an antiarrhythmic drug. Cardioversion is best reserved for

hastening onset of sinus rhythm once a drug like amiodarone has controlled rate. Cardioversion should at least be attempted within 24–48 hours of onset in the hope that embolic and anticoagulation issues are avoided.

MYOCARDIAL INFARCTION AND ARRHYTHMIA

Arrhythmia is common following AMI. While early arrhythmia contributes significantly to mortality, treatment is largely expectant and secondary to re-establishing coronary blood flow, minimising infarct size and treating ongoing ischaemia and heart failure. Late ventricular arrhythmia is particularly challenging, as selecting patients at risk is difficult and treatment options are limited.

MANAGEMENT OF ACUTE MYOCARDIAL INFARCTION AND ARRHYTHMIA CONTROL

Modern management of AMI, although targeted to prevent or reduce infarct size, has also been very effective in reducing arrhythmia incidence and sequelae. Numerous studies have documented transient ventricular arrhythmias at the time of reperfusion resulting from thrombolysis and acute angioplasty. However, the most common arrhythmias seen in this setting are VEB, AIVR and non-sustained VT, rather than VF or sustained VT.

Meta-analysis of thrombolytic trials has shown no increase in early VF following thrombolytic therapy in the first 24 hours. The likelihood of developing VF at any time during a hospital episode is reduced following thrombolytic therapy but the risk of developing VT is increased. The mechanism of reperfusion arrhythmia is believed to be related to intracellular calcium overload and the resulting triggered activity in the form of DAD. Dipyridamole, which inhibits the cellular uptake of adenosine, has been shown to be effective in preventing and treating reperfusion ventricular arrhythmia.

Prior to the introduction of thrombolytic therapy, beta-adrenergic receptor blockers significantly reduced the incidence of early VEB and VF. However, following routine use of thrombolytic therapy, the benefit of beta blockers relates to a reduction in post-infarction ischaemia and subsequent infarction.

The early work demonstrating survival benefit of magnesium was initially thought to be due to the prevention of arrhythmia.[70] However, the Leicester Intravenous Magnesium Intervention Trial (LIMIT-2) found the improved survival not to be related to a reduction in arrhythmia.[71] Subsequent studies in the thrombolytic era have failed to show any benefit at all with magnesium, although debate regarding optimal time of administration persists. Magnesium may have a role in patients in whom beta-adrenergic blockers or thrombolytic therapy are contraindicated.

ELECTROLYTE CONCENTRATIONS AND ARRHYTHMIA FOLLOWING ACUTE MYOCARDIAL INFARCTION

Serum potassium following AMI is negatively correlated with the incidence of VEB and VT, with the probability of VT falling until serum potassium exceeds 4.5 mmol/L.[9] There is no evidence that magnesium levels in this setting have any effect on ventricular arrhythmia. Nonetheless, ILCOR recommendations not only include the maintenance of serum potassium greater than 4.0 mmol/L, but also serum magnesium levels greater than 1.0 mmol/L.

BRADYARRHYTHMIAS POST ACUTE MYOCARDIAL INFARCTION

One-third of patients with AMI develop sinus bradycardia because of increased vagal tone. In inferior infarcts due to occlusion of the right coronary artery, bradyarrhythmia is due to ischaemia of the SA and AV nodes. Reperfusion of the right coronary artery can also lead to sinus bradycardia and heart block that is due to accumulation of adenosine in nodal tissue. Bradycardia in this setting is resistant to atropine.

Second- or third-degree AV block occurs in approximately 20% of AMI patients. High-degree AV block occurs early when present, with 42% presenting with AV block and most, 66%, developing in the first 24 h. Similar to all post-AMI arrhythmias, thrombolytic therapy has reduced the incidence down to 12%. When present, high-degree AV block is associated with an increased mortality. However, high-degree AV block is not an independent predictor, but rather a marker of extensive infarction and LV dysfunction.

Treatment is only indicated for sinus bradycardia associated with symptoms, hypotension or signs of poor cardiac output. Most often, first- and second-degree block also do not need treatment. Mobitz type I second-degree block may require treatment and atropine is indicated. However, in Mobitz type II, atropine usually has no effect on infranodal block and may precipitate third-degree block by increasing sinus rate and enhancing block. Atropine may improve heart rate with AV block occurring at the AV node, as demonstrated by a narrow QRS complex, by improving AV conduction or accelerating escape rhythm. Atropine is not indicated for infranodal third-degree block, which is diagnosed by the presence of a new wide QRS complex. When required, atropine is administered, 0.5–1.0 mg every 3 minutes until signs or symptoms are resolved, up to a maximum of 0.03–0.04 mg/kg. If atropine is not indicated or effective, cardiac pacing is required (**Box 22.4**). Transcutaneous pacing is indicated for initial management as a bridge until a transvenous temporary pacing wire can be inserted safely and with appropriate sterile technique. With the ready availability of transcutaneous pacing, i.v. catecholamines for

Box 22.4 Indications for pacing following myocardial infarction

Haemodynamically unstable bradycardia (<50 beats/min)

Bilateral bundle branch block
Left anterior fascicular block
New left bundle branch block
Bundle branch block and first-degree atrioventricular block

bradyarrhythmias are to be avoided in the setting of AMI.

ATRIAL FIBRILLATION POST ACUTE MYOCARDIAL INFARCTION

New-onset AF occurs in 10–15% of AMI. The incidence increases with age, large infarcts, LV hypertrophy and congestive cardiac failure. It is also related to atrial infarction with occlusion of the right coronary artery proximal to the sinus node branch or circumflex proximal to the left atrial circumflex branch. Later in the course of myocardial infarction, AF is related to postinfarct pericarditis.

Thrombolytic therapy has reduced the incidence of AF. In the setting of AMI, AF is usually self-limiting and requires no treatment. If rapid ventricular rates are associated with further ischaemic symptoms or haemodynamic compromise, cardioversion is indicated. Beta blockers, which are indicated in the treatment of AMI anyway, are the initial treatment of choice. Digoxin is not indicated in the setting of acute ischaemia as the likelihood of triggered activity associated with intracellular calcium overload is increased. AF following AMI is associated with an increase in mortality. Systemic emboli following AMI are three times more likely with AF and 50% occur in the first 24 hours of onset of AF. For this reason, sustained AF is an indication for anticoagulation prior to the normal 48-hour period following AMI.

VENTRICULAR ARRHYTHMIA POST ACUTE MYOCARDIAL INFARCTION[22,72,73]

VF/VT is the leading cause of mortality following AMI. Fifty per cent of patients dying from AMI do so pre-hospital due to VF/VT. Pre-hospital mortality is being reduced by improved community education, wider application of basic life support and availability of an automated external defibrillator (AED). Following admission to hospital, LV failure is the most common cause of death.

The major risk period for VF is the first 4 hours following onset of symptoms, with 4–18% of patients having VF in this period. Once admitted to hospital, 5% develop VF, mostly in this first 4-hour period. VF in this early 4-hour period is termed ‘primary VF’. VF later in the course of an AMI, usually associated with LV failure or cardiogenic shock, is called ‘secondary VF’.

Thrombolytic therapy has reduced VF incidence. The Gruppo Italiano per lo Studio della Streptochinasi nell’infarto miocardico (GISSI) study[72] found an incidence of primary VF of 3.6% and secondary VF of 0.6%. The overall incidence of ventricular arrhythmia in the Global Utilization of Streptokinase and Tissue plasminogen activator to treat Occluded arteries (GUSTO-1) report was VF, 4.1%, VT, 3.5% and both, 2.7%.

Primary VF increases in-hospital mortality and complications but not long-term mortality. Complex ventricular arrhythmias, defined as multiform VEB, couplets and non-sustained VT, occur in 35–40% of patients during hospital stay. They occur equally with Q-wave and non-Q-wave infarction. Complex ventricular arrhythmia is a risk factor for subsequent VF/VT and SCD, particularly in non-Q-wave infarction. Polymorphous VT is less common after AMI and does not appear to be related to QT prolongation or electrolyte disturbances in the reported cases.

Lidocaine reduces primary VF by 33% but mortality is increased by a similar amount such that there is no net benefit and the third International Study of Infarct Survival (ISIS-3) reported an overall trend to increased mortality.[74] Being more selective as to which patients receive lidocaine has not been possible, as only 50% of patients who develop VF have ‘warning’ ventricular arrhythmia. In the ‘percutaneous coronary intervention or thrombolytic and beta-blocker’ era of treatment of AMI, the use of prophylactic lidocaine, or any other antiarrhythmic drug, to prevent VF will have even less benefit. There are no conclusive data to support the use of lidocaine to prevent recurrent VF in those patients who have already suffered an episode of VF. Despite this, a short period of 6–24 hours of lidocaine has been advocated.

Patients who survive a late or secondary episode of VF/VT following myocardial infarction require full evaluation for preventive strategies, as do survivors of SCD. All survivors of a myocardial infarction are at an increased risk for SCD but accurate prediction is not feasible. Risk factors that have been shown to be associated with increased risk of a subsequent episode of VF/VT after myocardial infarction include:

- age
- Holter monitoring and demonstration of non-sustained VT, couplets and frequent VEB (i.e. >10 beats/min)
- impaired LV function (i.e. ejection fraction less than 30–40%)
- signal-average ECG and detection of delayed after-potentials. In patients presenting with SCD after myocardial infarction, 68–87% have an abnormal signal-average ECG. However, the positive predictive value is poor, at 15–25%

- demonstrated inducibility of VT postinfarction is associated with increased risk of SCD. However, the positive predictive value is again poor, at 20–30%.

Combinations of these risk factors have been evaluated to predict risk after infarction. The combination of delayed potentials on signal-average ECG, LV ejection fraction of less than 40% and non-sustained VT on Holter monitor has been shown to be associated with up to 50% risk of SCD. Currently, there is no agreement on which patients require primary preventive strategies for VF/VT following myocardial infarction.

Using frequent VEB to identify patients at risk following myocardial infarction has been extensively used. There have been 54 randomised trials reported involving more than 20 000 patients using 11 different class I agents.

Class I agents showed no overall benefit on all-cause mortality and class IC agents have excess mortality despite arrhythmia suppression.[15]

Class II antiarrhythmics, beta blockers, have an established and broadening role, with recent evidence showing significant benefit.[75]

Class III agents lack a consistent class effect. Sotalol (Survival with oral D-sotalol: SWORD) was found to increase all-cause mortality and arrhythmia deaths.[76] Amiodarone (Canadian Amiodarone Myocardial Infarction Arrhythmia Trial: CAMIAT) reduces all-cause mortality in patients with frequent VEB post myocardial infarction,[77] but another study (European Myocardial Infarction Amiodarone Trial: EMIAT) evaluated amiodarone in patients with ejection fraction less than 40% and found no effect on all-cause mortality but a 35% reduction in arrhythmia deaths.[78] Subsequent analysis of combined CAMIAT and EMIAT data has emphasised the importance of beta blockers. The combination of amiodarone and beta blockers in these post-infarct patients was better than either drug alone.[79]

CARDIOTHORACIC SURGERY AND ARRHYTHMIA

SVT AFTER CARDIOTHORACIC SURGERY[80]

AF predominates, with Afl and unifocal atrial tachyarrhythmia also commonly occurring after coronary artery bypass grafting, with an incidence of 11–40% and in over 50% following valvular surgery. In addition to mechanisms found in non-surgical patients, pericardial inflammation or effusion, increased catecholamine production and postoperative autonomic changes are implicated. Major risk factors include:

- previous history of AF
- increasing age
- postoperative withdrawal of beta-blocker therapy.

Extent of coronary artery disease, postoperative ischaemia, duration of aortic cross-clamping or cardiopulmonary bypass and method of myocardial protection do not influence incidence. SVT post cardiothoracic surgery is not a benign event, with the major consequence being thromboembolic complications. Stroke occurs following coronary artery bypass grafting in 1–6% of patients and postoperative atrial tachyarrhythmia increase the incidence threefold. Other adverse effects include:

- haemodynamic instability
- prolonged inotropic support
- need for intra-aortic balloon pump
- reoperation for bleeding
- longer and more expensive critical care unit and hospital episodes.

PREVENTION OF SUPRAVENTRICULAR TACHYCARDIA[81,82]

Preoperative beta-blocker treatment should be continued postoperatively. Beta blockers consistently reduce SVT across many studies with differing agents.

Amiodarone prophylaxis after elective cardiac surgery reduced postoperative AF from 53% to 25%. Diltiazem has also been shown to be effective at SVT prevention and there was associated improvement in haemodynamic variables and rates of myocardial ischaemia. Verapamil is not effective. Esmolol was found to be more effective than diltiazem. Sotalol is also effective but problematic bradycardia and hypotension are greater.[83] Atorvastatin is also effective.[84]

There is no relation between SVT incidence and serum magnesium levels and there are conflicting data relating to the efficacy of prophylactic magnesium. Digoxin has no role in prevention.

TREATMENT OF SUPRAVENTRICULAR TACHYCARDIA

Treatment is aimed at control of ventricular rate, prevention of thromboembolism and cardioversion.

Digoxin, atenolol, diltiazem and magnesium are appropriate choices to control rate.

In persisting AF, the timing of electrical cardioversion is debatable. Early electrical cardioversion, inside 24–48 hours, avoids the need for anticoagulation but is associated with a significant recurrence rate as postoperative arrhythmogenic factors remain. In persistent or recurrent AF, sotalol and amiodarone, depending on myocardial function, are suitable antiarrhythmic drugs and should be continued for 6–12 weeks following cardioversion.

Timing of safe anticoagulation following cardiac surgery is also debatable. Many advocate delaying anticoagulation till 72 hours post surgery, which may be greater than 24–48 hours after onset of SVT. Most cardiac surgical patients receive aspirin and low-dose heparin in the early postoperative period, which is likely to reduce risk. However, it is worth noting that, in other AF settings, 325 mg of aspirin decreased thromboembolic events but 75 mg did not.

VENTRICULAR ARRHYTHMIA FOLLOWING CARDIAC SURGERY

Ventricular arrhythmia requiring treatment, DC shock or drug therapy is common following cardiac surgery and occurs in 23% of patients.[85] Arrhythmias requiring DC shock occur in the first 36 hours and are associated with:

- advanced age
- failure to use an internal mammary artery conduit (which is likely to reflect preoperative assessment of high risk)
- SVT.

The incidence was not related to previous myocardial infarction, ejection fraction of less than 50%, prolonged operative time, perioperative myocardial infarction or reduced number of vessels bypassed. In patients undergoing coronary artery bypass, grafting patients at high risk for sudden death, LV ejection fraction less than 36% and abnormalities on signal-averaged ECG had a 6.3% incidence of sustained VT and 4.3% VF.

VEBs are common early on return from surgery, with frequent or complex ectopy associated with adrenergic effects of emerging from anaesthesia and hypokalaemia. The threshold to treat these arrhythmias varies with clinicians. Potassium must be regularly checked and maintained above 4 mmol/L.

If there is accompanying emergent hypertension, in addition to the antiarrhythmic action, the vasodilating properties of magnesium provide an ideal profile at this stage. Patients with VT/VF reverting with DC shock who are haemodynamically stable should have prophylactic antiarrhythmic cover until adrenergic stimulation associated with awakening and weaning from mechanical ventilation is past. Lidocaine has been the agent of choice, but magnesium, amiodarone and sotalol are all more effective. Maintaining antiarrhythmic levels of magnesium may not be conducive to weaning from ventilation. Extrapolating from post myocardial infarct data would support the conversion to beta blockers if there were no contraindications.

A smaller proportion of patients develop malignant VF/VT, most often in association with poor LV function and a postoperative low-cardiac-output state requiring catecholamine infusions. In this setting, ventricular arrhythmia is common, often initiated by short-coupling polymorphous VT (normal QT_c), due to ongoing ischaemia or reperfusion of ischaemic heart.

- High-dose amiodarone may work best in combination with antiarrhythmic levels of magnesium (1.8–2.0 mmol/L) or lidocaine.
- Many of these patients need an intra-aortic balloon pump to defend coronary artery perfusion pressure not only because of the likely poor LV function and low-output state, but also to minimise the adverse affects of antiarrhythmic drugs and recurrent DC shocks.
- Pacing may be required to counteract bradyarrhythmia associated with escalating doses of antiarrhythmic drugs. Pacing at faster rates (90–110 beats/min, which may not be ideal from a cardiac-output point of view) may be protective against recurrent episodes by promoting homogeneity of depolarisation and suppression of abnormal automaticity. The presence of epicardial or transvenous pacing wires also enables bedside-programmed stimulation and overdrive pacing for termination of recurrent VT, which has fewer deleterious effects than recurrent DC shocks.

LONG-QT SYNDROME

The traditional criteria of prolonged QT needs to be corrected for heart rate (QT_c, Bazett's formula, QT divided by the square root of the RR interval) and a QT_c greater than 0.44 ms. Borderline QT_c is common and stems from miscalculation in the setting of atypical T-waves and prominent U-waves. The recommended method to determine the end of the T-wave is by intersecting the tangent to the steepest slope of the last limb of the T-wave and the baseline (**Fig. 22.50**). The diagnosis of 'borderline LQTS' is common with QT_c in the range of 440–470 ms. QT_c should also be adjusted for age and gender with females an average 10 ms longer. There is significant overlap between the normal population and patients with congenital LQTS; 25–35% of congenital LQTS have a QT_c<440 ms (**Fig. 22.51**).

The causes of LQTS can be divided into acquired and congenital (**Box 22.5**). Most drugs that cause LQTS do so by binding to the HERG or alpha subunit of the I_{Kr} potassium channel and reducing repolarisation current. Unlike other I_K potassium channels, the HERG subunit of I_{Kr} is very sensitive to unintended drug binding owing to aromatic amino acids positioned in such a way as to block the channel. Common to all causes is a prolongation of repolarisation, which creates the substrate for random re-entry giving rise to polymorphous VT (classically of the torsade de pointes type), particularly under conditions of acute adrenergic arousal.

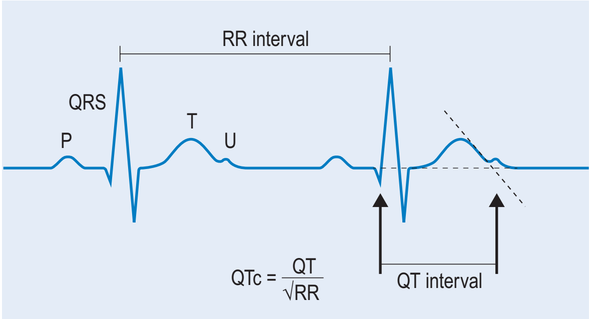

Figure 22.50 Determining QTc using the 'tangent method'.

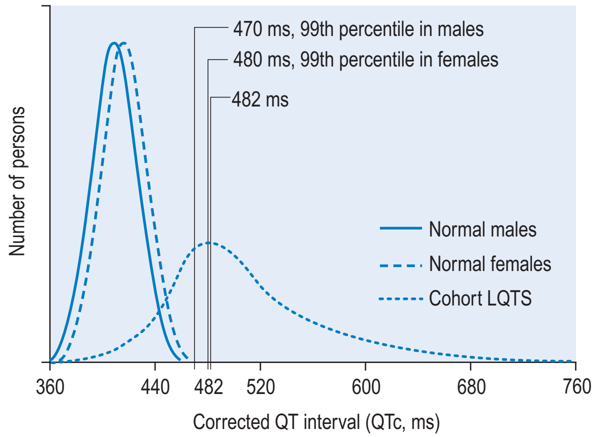

Figure 22.51 Distribution of QTc values (adapted from Johnson et al[87]). 99th percentile males 470 ms. 99th percentile females 480 ms. There is significant overlap of these 'normal' QTc persons and a cohort of mutation-positive patients, mean QTc 482 ms. *(From Taggart NW, Haglund CM, Tester DJ, et al. Circulation 2007;115:2613–20,[106] with permission.)*

Action potential prolongation results from either enhancing depolarisation (sodium (Na) channel, I_{Na}) or reducing repolarisation current (delayed rectifier potassium (K) currents, I_{Kr} and I_{Ks}).

There is less capacity to respond to additional stresses that impair repolarisation such as hypokalaemia, hypomagnesaemia and drugs with class III action.

Prolonged action potential in LQTS predisposes to arrhythmia in two ways:

1. Extended plateau phase of action potential results in susceptibility to EAD-initiated arrhythmia. EADs are due to re-opening of L-type calcium channels, the activity of which is increased by adrenergic stimulation, which explains the association between sudden cardiac death and exercise and excitement in LQTS.
2. Heterogeneity of prolonged action potential creates spatial dispersion of repolarisation, leading to regions of refractory block and substrate for re-entrant arrhythmia. This mechanism appears important in pharmacological LQTS.

CONGENITAL LQTS[88]

Congenital LQTS is a collection of genetically distinct arrhythmogenic disorders resulting from genetic mutations in cardiac potassium and sodium ion channels giving rise to the term 'cardiac channelopathies'. As there is overlap in QT_c between the normal population and congenital LQTS patients, a LQTS clinical probability score has been developed to determine probability of diagnosis (**Table 22.12**).

Congenital LQTS results from mutations in genes coding for cardiac proteins including ion channels, accessory subunits and modulatory proteins (**Table 22.13**).

Box 22.5 Causes of long-QT syndrome

Acquired
Drugs
- Class IA antiarrhythmic drugs
- Quinidine, procainamide
- Class III antiarrhythmic drugs
- Amiodarone, sotalol
- Tricyclic antidepressants
- Macrolide antibiotics
- Phenothiazines
- Antihistamines
- Cisapride

Myocardial ischaemia/infarction
Hypokalaemia
Cardiomyopathy
Acute myocarditis
Mitral valve prolapse
Acute cerebral injury
Hypothermia

Congenital
Familial
90%
Linked to a DNA marker on the short arm of chromosome 11
Autosomal-dominant in most cases
Some cases linked to congenital deafness and autosomal-recessive
Non-familial – related to new gene mutation
Sporadic: 10%

CLINICAL FEATURES[89]

Prevalence is estimated to be 1 in 2500–5000.

Thirty per cent of patients with congenital LQTS present with unexplained syncope or aborted sudden death (which is often not the first episode). The majority (60%) are identified when family members are screened after syncope or cardiac arrest in a family member. Ten per cent are detected on routine evaluation of ECG. The majority of episodes of syncope or sudden death (60%) are precipitated by emotions, physical activity or auditory stimuli causing acute adrenergic arousal. The degree of QT_c prolongation is not predictive of syncope or sudden death.

MANAGEMENT

The first line of management of polymorphous VT with shock is DC shock, with magnesium being the antiarrhythmic of choice.[90]

- Unresponsive rhythms or recurrence despite magnesium require pharmacological intervention (isoproterenol (isoprenaline) or epinephrine (adrenaline) depending on blood pressure) or electrical pacing.
- Factors associated with acquired LQTS need to be identified and eliminated.

Table 22.12 LQTS clinical probability score

FINDING	POINTS
HISTORY	
Syncope	
– without stress	1
– with stress	2
Congenital deafness	0.5
Family history of LQTS	1
Unexplained sudden death in a first-degree family member <age 30	0.5
ECG	
QTc by Bazett's formula	
450–459 ms in males	1
460–479 ms	2
≥480 ms	3
Torsades des pointes	2
T-wave alternans	1
≥3 leads with notched T-waves	1
Bradycardia <2nd centile for age	0.5
PROBABILITY SCORE	≤1 low probability >1 to <4 intermediate probability ≥4 high probability

Schwarlz PJ, Moss AJ, Vincent GM, et al. Diagnostic criteria for the long QT syndrome. An Update. Circulation 1993; 88:782–4.[107]

Strategies for prevention of recurrence in congenital LQTS depend on the presentation. Patients who present with or have a history of syncope or aborted sudden death have a high risk of recurrence (5% per year). Beta blockers are the first line of treatment with the goal of reducing the exercise heart rate to less than 130 beats/min. Symptomatic bradycardia following adequate beta blockade requires a permanent pacemaker. Patients with recurrence despite these measures and those with an early malignant course need stellate sympathetic ganglionectomy. In 5% of these high-risk patients triple therapy fails and an implantable defibrillator is required. Asymptomatic patients with incidental LQTS (<0.5% per year) and asymptomatic family members (0.5% per year) have a very low risk of syncope or sudden death. It is also very rare for the first episode to be fatal in these two groups so prophylactic measures are generally not required and close follow-up is sufficient.

Class IA, IC and III drugs may increase QT interval and should be avoided in polymorphous VT and torsade de pointes.

SUDDEN CARDIAC DEATH

Arrhythmic causes of SCD can be divided into three categories:

Table 22.13 Classification of congenital LQTS

TYPE	GENE MUTATION/ PROTEIN	FEATURES
LQT1	KCNQ1 α–subunit of I_{KS}	Reduced function of I_{KS} decreases repolarising current Most common at 30–35% but less severe When homozygous associated with congenital deafness
LQT2	KCNH2/h ERG α–subunit of I_{Kr}	Reduced function of I_{Kr} decreases repolarising current 25–30%
LQT3	SCN5A α–subunit of I_{Na}	Increased function of I_{Na} prolonging depolarising Na current Mutations in SCN5A also cause Brugada syndrome, cardiac conduction disease and dilated cardiomyopathy
LQT4	Anchor protein ankyrin B	Ankyrin B anchors ion channels in the cell
LQT5	KCNE1 β–subunit of I_{Ks}	Reduced function of I_{Ks} Homozygous leads to Jervell and Lange–Nielson syndrome Congenital deafness
LQT6	KCNE2 β–subunit of I_{Kr}	Reduced function of I_{Kr}
LQT7	K-channel I_{KI}	Anderson–Tauvel syndrome Associated skeletal deformities
LQT8	C_{AV} CACNAIc $I_{ca\text{-}L}$	Calcium channel is distributed widely Timothy's syndrome Multiple clinical manifestations

1. *VT or VF:* this is most common.
2. *SVT with a very rapid ventricular rate:* this is usually associated with the development of AF or flutter in the presence of an accessory AV connection (but can occasionally be due to enhanced conduction over the normal AV conduction system).
3. *Bradycardia or asystole:* this is usually the result of an inadequate escape pacemaker mechanism associated with either a high-degree AV block or severe sinus node dysfunction. In addition, some patients with sinus node dysfunction have paroxysmal supraventricular arrhythmia (tachycardia–bradycardia syndrome) that on termination results in an exaggerated overdrive suppression of both the sinus node and escape pacemakers such that the prolonged pause evolves into asystole or VF.

The causes of these arrhythmias can be divided into three general categories:

1. *Ischaemic heart disease:* AMI or old myocardial infarction scar
2. *Non-ischaemic heart disease:* cardiomyopathy, valvular heart disease, congenital heart disease, ventricular hypertrophy and cardiac trauma
3. *No apparent structural heart disease:* primary electrical disease, electrolyte abnormalities, LQT syndromes and drugs.

Contributing factors are often multifactorial, particularly the combination of structural heart disease, proarrhythmic drugs and electrolyte abnormalities.

EVALUATION OF A SURVIVOR OF SCD

Primary prevention of SCD has been disappointing owing to difficulties in selecting patients at risk. Regardless of the aetiology of the SCD, the reported recurrence rate is high, at least 30–40% at 1 year. Therefore, in-hospital assessment is critical to establish the underlying cause and to guide therapy.

CORONARY ARTERY DISEASE AND SUDDEN CARDIAC DEATH

Extensive atherosclerotic coronary artery disease is the most common pathological finding in survivors and non-survivors of SCD. Fewer than 30% have evidence of a recent AMI. A larger proportion (up to 50%) has evidence of coronary artery thrombosis or plaque fissuring and rupture. In those patients not having an AMI, the majority (75%) has a coronary artery stenosis (> 50% of lumen), and 60% have three-vessel disease. Approximately 50% have evidence of an old myocardial infarction. The fact that the typical pathological background for SCD is severe epicardial coronary artery disease, with or without an old myocardial infarction and evidence of a new ischaemic syndrome, underlines the central role that coronary artery disease plays in SCD.

INVESTIGATIONS[17–19]

- *Chest X-ray:* cardiac size, presence of pulmonary oedema.
- *12-lead ECG:* acute ischaemia, previous infarction, ventricular aneurysm or LV hypertrophy. Abnormalities of rate, rhythm, conduction or sinus node dysfunction. PR interval, QRS complex duration or QT interval. Changes of electrolyte abnormalities.
- *Plasma electrolytes:* potassium, magnesium and calcium. Potassium levels may be difficult to interpret after a period of resuscitation.
- *Cardiac enzymes:* serial troponin T, creatinine phosphokinase with myocardial band fractionation and lactate dehydrogenase to establish the presence of a recent AMI.
- *Plasma blood levels of drugs that affect cardiac rhythm or conduction:* while proarrhythmic effects of drugs are more likely at high levels, it should be emphasised that proarrhythmia can occur at normal or low plasma drug levels.
- *Toxicology screen:* substance abuse or drug overdose (cocaine, psychotropic drugs), particularly in patients without overt structural heart disease.
- *24-hour Holter monitor ECG:* quantitative analysis of frequency of arrhythmia and to detect silent myocardial ischaemia.
- *Assessment of LV function:* LV ejection fraction. Gated pool scan gives a better estimate of global LV systolic function, but echocardiogram will give added diagnostic information such as valvular disease and myocardial hypertrophy. Both studies will detect segmental wall motion abnormalities.
- *Exercise tolerance test:* standard exercise ECG or thallium-201 scans. Echocardiogram immediately following exercise may be as informative.
- *Signal-average ECG:* averages between 100 and 400 heart beats, for identification of low-amplitude electrical signals, such as after-depolarisations. These are found in the terminal portion of the QRS complex and cannot be seen on the 12-lead ECG. Associated with an increased risk of spontaneous and inducible ventricular arrhythmia.
- *Cardiac catheterisation and coronary angiogram:* to quantify the degree of coronary artery disease.
- *EPS:* virtually always indicated to document and characterise ventricular tachyarrhythmia. The initial baseline EPS should be performed in the absence of any antiarrhythmic drugs. Inducibility of sustained ventricular arrhythmias at EPS is associated with worse outlook, with a 5-year risk of SCD of 32% versus 24% in those without inducible arrhythmia, and is an indication for an implantable defibrillator. The inducibility of VT/VF is less common in survivors of SCD (44%) than patients who present with recurrent sustained VT. In patients with sustained monomorphic haemodynamically stable VT, EPS mapping techniques are used to determine the possibility of surgical or catheter ablation. EPS is also important in other causes of SCD other than VT/VF. Patients with ventricular pre-excitation (WPW syndrome) require localisation of the accessory pathway. Propensity to develop complete heart block can be assessed by a His-bundle ECG.

PREVENTION OF RECURRENT VENTRICULAR ARRHYTHMIA IN SURVIVORS OF SUDDEN CARDIAC DEATH

MYOCARDIAL REVASCULARISATION AND SUDDEN CARDIAC DEATH

The Coronary Artery Surgery Study (CASS) registry looked at 13 476 patients with significant operable

coronary artery disease and showed an incidence of SCD of 5.2% in the medical arm compared with 1.8% in those assigned to surgery.[92] The precise mechanism of the benefit of surgery in primary prevention is unclear but is probably associated with prevention of ischaemia rather than arrhythmia control. In summary, the near-universal practice of surgical coronary revascularisation in SCD survivors with critical stenoses is based upon this primary prevention data (and the central role that ischaemia and infarction are known to play in arrhythmia substrate) rather than data demonstrating arrhythmia control.

ANTIARRHYTHMIC DRUGS AND SUDDEN CARDIAC DEATH[15,76–79]

The CAST study has clearly demonstrated the poor results of antiarrhythmic drug therapy alone in the prevention of arrhythmic SCD. Data from studies in survivors of SCD using amiodarone are conflicting, but generally poor, even with EPS confirmation of lack of inducibility. Certainly patients with an ejection fraction less than 30% do poorly on amiodarone alone. The primary role of antiarrhythmic drugs in the secondary prevention of SCD has all but disappeared, but amiodarone may be indicated if there is demonstrable suppression of inducible VT at EPS and the patient has an ejection fraction greater than 30–40%.

SURGICAL AND CATHETER ABLATION TECHNIQUES AND SUDDEN CARDIAC DEATH[27]

As most sustained ventricular arrhythmias arise from a scar within the myocardium, surgical attempts were made to excise these areas completely. Catheter ablation techniques for VT are suitable for the minority of patients with haemodynamically stable VT who can withstand prolonged mapping procedures. Currently, the success rates for ablative techniques are such that a significant number still need additional preventive therapies.

IMPLANTABLE CARDIOVERTER DEFIBRILLATORS AND SUDDEN CARDIAC DEATH

The reduction in SCD and overall cardiac mortality with implantable cardioverter defibrillators (ICDs) has been so spectacular and the results of previous therapies so poor that ICDs were initially introduced with little randomised controlled data. More recently controlled studies have shown:

- reduction in 3-year mortality by 31% compared to antiarrhythmic drug therapy in SCD survivors[93]
- reduced risk of death in patients with poor LV function following myocardial infarction[94]
- improved survival in patients with hypertrophic cardiomyopathy.[95]

However, no survival benefit was shown in high-risk patients following coronary artery bypass surgery.

Table 22.14 Mortality data for the various treatment regimens for sudden cardiac death

	SUDDEN DEATH (%)	TOTAL MORTALITY (%)
Implantable cardioverter defibrillator	3.5	13.6
Empirical amiodarone	12	34
Electrophysiological study-directed drug treatment	14	24
Surgery	3.7	37

Representative data from several studies are shown in **Table 22.14**. The benefit of ICD on survival persists for at least 8 years. Current indications are expanding, but the benefit is clear in the following groups of survivors of SCD and patients with documented VT/VF outside the early post-infarct phase:

- non-inducible VT/VF at EPS
- inducible VT/VF resistant to treatment
- VT/VF in patients with LV ejection fractions less than or equal to 30% regardless of results of EPS-directed drug therapy.

Further developments currently taking place include:

- transvenous catheter placement and subcutaneous patch avoiding the need for thoracotomy
- dual-chamber sensing to improve discrimination between SVT and VT that can be difficult on rate criteria alone, particularly in patients with intraventricular conduction delay
- technological advances reducing size, cost and increasing battery life.

Although one of the proposed advantages of ICD is the avoidance of antiarrhythmic drug side-effects, particularly the myocardial depressant effects, current practice usually combines ICD with low-dose amiodarone. This enables improved arrhythmia control by reducing atrial tachyarrhythmia and slowing VT rate, and prolonging battery life by reducing the frequency of arrhythmia. The role of ICD in the management algorithms of SCD is shown in **Figures 22.52** and **22.53**. Given the current lack of available ICD, some advocate restriction to patients less than 75 years. With wider availability of ICD, fewer patients will be managed on drug-only strategies in the future.

CLASSIFICATION OF ANTIARRHYTHMIC DRUGS

The time-honoured physiologically based classification of antiarrhythmic drugs is the Vaughan-Williams

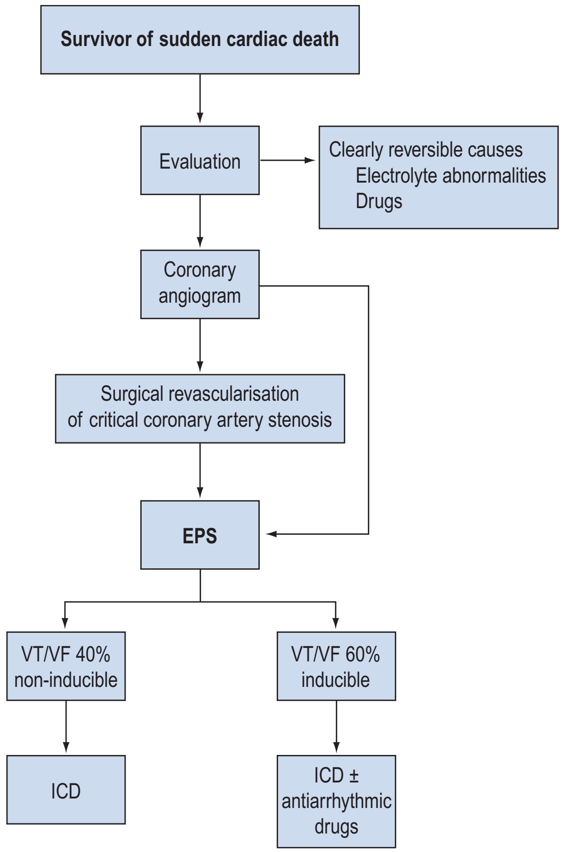

Figure 22.52 Management algorithm of a survivor of sudden cardiac death. This algorithm does not include the option of an antiarrhythmic drug alone in patients with intact left ventricular function who initially have inducible ventricular tachycardia/fibrillation (VT/VF) that is subsequently found to be suppressible on a drug with electrophysiological studies (EPS). ICD, implantable cardioverter defibrillator.

classification (**Table 22.15**), which has been modified over the years. This classification is a hybrid, with classes I and IV representing ion channel blockers, class II representing a receptor blocker and class III representing a change in an electrophysiological variable. The prolongation of repolarisation, the defining effect of class III agents, can be produced by a block of any one of several K^+ ionic channels (the delayed rectifier potassium current I_{Kr} responsible for phase 3 repolarisation is the ionic channel target of most class III agents) or from modification of Na^+ or Ca^+ channel function. This classification is also incomplete and does not include cholinergic agonists, digitalis, magnesium and adenosine. For this reason, an alternative classification has been advocated based upon molecular targets for drug action that include ion channels, receptors and pumps/carriers (**Table 22.16**).[3]

Table 22.15 Vaughan-Williams classification of antiarrhythmic drugs

CLASS	MECHANISM OF ACTION	EFFECT ON ACTION POTENTIAL	INDICATIVE DRUGS
Class I	Sodium channel blockers	Depresses rate of phase 0 depolarisation	
Class IA		Prolongs repolarisation	Procainamide Disopyramide Quinidine
Class IB		Shortens repolarisation	Lidocaine Mexiletine Phenytoin
Class IC		Minimal effect on repolarisation	Flecainide Encainide Propafenone
Class II	β-adrenergic receptor blockers		Propranolol Atenolol Metoprolol Esmolol
Class III	Potassium channel blockers	Prolongs repolarisation	Amiodarone Dronedarone Sotalol Ibutilide Vernakalant Bretylium
Class IV	Calcium channel blockers		Verapamil Diltiazem

ANTIARRHYTHMIC DRUGS

DIGOXIN

Digoxin is a muscurinic subtype 2 receptor (M_2) agonist and a highly potent Na^+/K^+-ATPase pump-blocking agent. Digoxin exerts its antiarrhythmic activity predominantly at the AV node where at lower doses conduction is slowed by the M_2 vagotonic effect. This effect is easily reversed by enhanced sympathetic tone in the setting of exercise, critical illness and postoperative state. At higher concentrations, digoxin has a direct effect on AV node conduction by the Na^+/K^+-ATPase pump blockade and is more resistant to sympathomimetic effects. The decrease in $[K^+]_i$ and increase in $[Na^+]_i$ results in hyperpolarisation, shortening of atrial action potential and an increase in AV nodal refractoriness. There is also increased availability of intracellular Na^+ for the Na^+–Ca^{2+} exchanger, increasing $[Ca^{2+}]_i$ which results in the positive inotropic effects of digoxin, making it an ideal agent in the setting of LV dysfunction. However, the positive inotropic effects

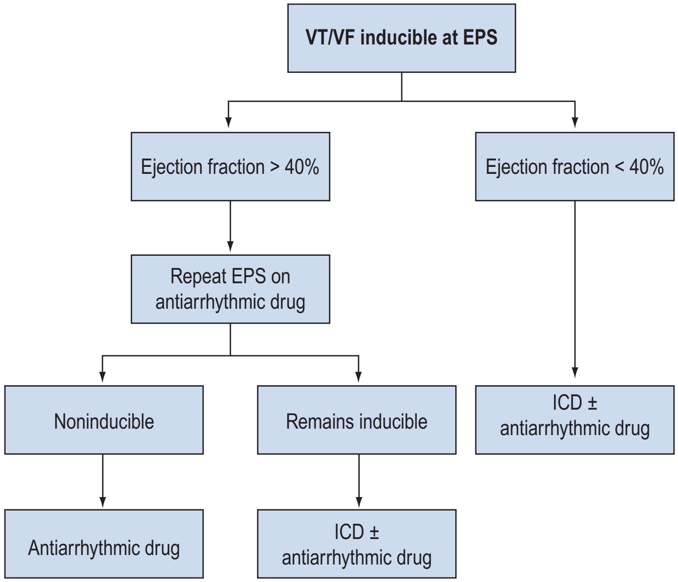

Figure 22.53 Patients found to have inducible ventricular tachycardia (VT) or fibrillation (VF) at electrophysiological studies (EPS), with an ejection fraction >40% and subsequent drug suppression of their VT/VF, can be managed on antiarrhythmic drugs alone.

of Na^+/K^+-ATPase blockade are deleterious in the setting of myocardial ischaemia and other causes of diastolic dysfunction. Digoxin also has weak vasopressor properties when administered as a slow bolus.[6] The major ECG effects of digoxin are PR prolongation and a non-specific alteration in ventricular repolarisation with characteristic reverse-tick S-T segments.

INDICATIONS AND DOSE

- *AF:* slowing of ventricular rate only
- *Loading dose:* 15 µg/kg i.v., typically administered over 30–60 min, but can be given faster
- *Maintenance dose*: depends on renal function.

PLASMA LEVELS

Oral bioavailabiliy can be reduced, especially if intestinal microflora-altering antibiotics are co-administered. Therapeutic levels are 0.5–2.0 ng/mL. Plasma levels must be measured during the post-distribution phase some 6–8 hours after dose. The elimination half-life is 36 hours with normal renal function. Difference between therapeutic and toxic levels can be reduced by hypokalaemia, hypomagnesaemia, hypercalcaemia, hypoxia, cardiac surgery and myocardial ischaemia. Many drugs increase digoxin plasma levels by competing with the renal P-glycoprotein-mediated transport, or by reducing renal blood flow or function.

CONTRAINDICATIONS

Relative contraindications include myocardial ischaemia/infarction, diastolic heart failure due to hypertrophy and ischaemia, renal failure and hyperkalaemia, planned DC shock cardioversion and tachycardia–bradycardia syndromes. Co-administration with other drugs that effect AV nodal conduction, typically beta-adrenergic and calcium channel blockers requires caution.

ADVERSE EFFECTS

The same increase in $[Ca]_i$ responsible for the positive inotropic effects of digoxin also forms the basis for toxicity arrhythmia. The increased inward calcium current is responsible for DAD-initiated arrhythmia. Digoxin toxicity can cause virtually any arrhythmia:

- DAD-related tachycardia with impairment of sinus node or AV nodal function
- unifocal atrial tachycardia with AV block is 'classic'
- ventricular bigeminy and various degrees of AV block occur.

With advanced toxicity severe hyperkalaemia due to poisoning of Na^+/K^+-ATPase results. Profound bradycardia, which may be unresponsive to pacing, develops.

Any serious toxicity arrhythmia should be treated with antidigoxin Fab fragments. Magnesium is the drug of choice for digoxin-toxic tachyarrhythmia. Digoxin, particularly at toxic levels, increases risk of VF precipitated by DC shock. Digoxin toxicity is associated with nausea, disturbances in cognitive function and blurred or yellow vision (xanthopsia).

BETA-ADRENERGIC BLOCKERS

Beta-adrenergic blocking or class II antiarrhythmic drugs have differing properties such as relative cardioselectivity (atenolol, metoprolol), non-cardioselectivity (propranolol), intrinsic sympathomimetic activity (pindolol), lipid solubility and

Table 22.16 Actions of antiarrhythmic drugs on membrane channels, receptors and ionic pumps in the heart

Sodium channel blockers are subdivided into drugs with fast, medium and slow time constant for recovery from block. Receptors: α-, β-adrenoreceptors, M_2=muscarinic subtype 2; P=A_1 purinergic. Relative blocking potency: +=low; ++=moderate; +++=high; +/−=partial agonist/antagonist; A=agonist.

central activity (metoprolol, propranolol) and membrane-depressant effects (propranolol). The antiarrhythmic properties appear to be a class effect and no agent has been shown to be superior. There are data to suggest that the survival benefit of beta-adrenergic blockers post myocardial infarction may relate to some extent to the central modulation of autonomic tone of the more lipid-soluble agents. The direct membrane-stabilising or 'quinidine-like' effect of propranolol requires doses far greater than those used clinically and is of negligible clinical significance. Beta-adrenergic blockers competitively inhibit catecholamine binding at the beta-adrenergic receptor sites, which reduces the phase 4 slope of the action potential of pacemaker cells, prolongs their refractoriness and slows conduction in the AV node. Refractoriness and conduction in the His–Purkinje system are unchanged. Beta-adrenergic blockers are most effective in arrhythmia associated with increased cardiac adrenergic stimulation (postoperative states, sepsis, thyrotoxicosis, phaeochromocytoma, exercise or emotion).

INDICATIONS

Supraventricular tachycardia

Beta-adrenergic blockers may terminate SVT when the AV node is an intrinsic part of the re-entry circuit (AVNRT and AVRT); adenosine is more effective. AF and Afl do not revert with beta-adrenergic blockers, but the ventricular rate will be slowed. Beta-adrenergic blockers are effective at preventing SVT following cardiac surgery. Studies involving propranolol and atenolol have produced the best results. Beta-adrenergic blockers are effective in MAT, but, as this arrhythmia is most often seen in patients with severe chronic airflow limitation and cor pulmonale, their utility is limited.[31]

Ventricular arrhythmias

Beta-adrenergic blockers are ineffective for the emergency treatment of sustained VT. Empiric prophylactic administration of beta-adrenergic blockers appears to be as effective in ventricular arrhythmia prevention as electrophysiologically guided drug methods. However, ventricular arrhythmia most often occurs in the setting of poor LV dysfunction and beta-adrenergic blockers are either poorly tolerated or contraindicated.

Myocardial infarction

Survival in patients with AMI treated with thrombolytics is probably improved by early i.v. beta-adrenergic blockade. There may be other benefits such as decreased incidence of VF and relief of chest pain. Long-term beta-adrenergic blockade reduces mortality following myocardial infarction, the benefit being greatest in those at highest risk for sudden death. However, suppression of ventricular ectopy is not a requisite for benefit. Drugs with intrinsic sympathomimetic activity have not been shown to improve survival after AMI.

ATENOLOL

Atenolol does not have significant central action due to poor lipid solubility and is eliminated predominantly by the kidneys with an elimination half-life of 7–9 hours. Care is required in patients with poor or deteriorating renal function.

- *Loading dose i.v.:* 5 mg every 10 min, maximum 10 mg
- *Loading dose oral:* 50–100 mg
- *Maintenance dose oral:* 50–200 mg/day
- *ISIS-1 post-MI regimen:* 5 mg i.v. over 5 min, repeated 10 min later if heart rate exceeds 60 beats/min. If heart rate exceeds 40 beats/min 10 min later, oral 50 mg atenolol and continue at 100 mg daily
- *SVT prophylaxis following cardiac surgery:* 5 mg i.v. within 3 hours of surgery, repeated 24 hours later, followed by oral 50 mg daily for 6 days.

METOPROLOL

Metoprolol is lipid-soluble and has significant central action. It is eliminated by the liver with an elimination half-life of 3–4 hours.

- *Loading dose i.v.:* 1–2 mg/min, maximum dose of 15–20 mg
- *Loading dose oral:* 100–200 mg
- *Maintenance dose oral:* 50–100 mg/12-hourly.

PROPRANOLOL

Propranolol has been one of the most studied beta-adrenergic blockers for SVT prophylaxis following cardiac surgery.

- *Dose:* 10 mg orally 6-hourly starting the morning after surgery.

ESMOLOL

Esmolol is an ultrashort-acting cardioselective beta-adrenergic blocker, which is especially useful for rapid control of ventricular rate in AF or Afl. Esmolol has also been shown to prevent postoperative SVT. The distribution half-life is 2 minutes and the elimination half-life is 9 minutes. Esmolol is rapidly metabolised by hydrolysis of the ester linkage, chiefly by the esterases in the cytosol of red blood cells and not by plasma cholinesterases or red cell membrane acetyl-cholinesterase:

- *Loading dose i.v.:* 500 μg/kg over 1 min
- *Maintenance dose i.v.:* 50 μg/kg per min for 4 min. If satisfactory rate control is not achieved, the loading dose should be repeated and the maintenance dose increased to 100 μg/kg per min. If control is still not achieved after a further 4 min, then the procedure is repeated with 50 μg/kg per min increments in the maintenance infusion until 300 μg/kg per min is reached. Further increases in infusion rate are unlikely to be successful.

CONTRAINDICATIONS

Reversible airways disease and poor LV function are two common relative contraindications, which limit the utility of beta-adrenergic blockers in patients with cardiac disease. Beta-adrenergic blockers may also be poorly tolerated in diabetics and patients with severe peripheral vascular disease.

ADVERSE EFFECTS

Beta-adrenergic blockers, particularly those that are centrally acting, are often poorly tolerated in the long term. These effects include fatigue, hypotension, bradycardia, dry mouth, dizziness, headache and cold extremities.

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers or class IV antiarrhythmic drugs block the slow calcium channels in cardiac tissue. Verapamil and diltiazem have similar electrophysiological properties. The dihydropyridine group of calcium channel blockers, which include nifedipine, does not have any significant electrophysiological properties. Calcium channel blockers depress the slope of diastolic depolarisation in the SA node cells, the rate of rise of the phase 0 and action potential amplitude in the SA and AV nodal cells. They also slow conduction and prolong the refractory period of the AV node, which results in their main antiarrhythmic actions. Refractoriness of atrial, ventricular and accessory pathway tissue is unchanged. The sinus rate does not usually change significantly because calcium channel blockers induce peripheral vasodilatation, which causes reflex sympathetic stimulation of SA node. Verapamil particularity has marked negative inotropic actions and hypotension is often seen; however, cardiac index is generally maintained because of afterload reduction. Diltiazem has a less negative inotropic effect than verapamil.

INDICATIONS

- *SVT:* calcium channel blockers are effective if the AV node is an integral part of the arrhythmia circuit. Verapamil has been superseded by adenosine for the first line of treatment for these with AVNRT and AVRT
- *AF and Afl:* slow ventricular response in AF and Afl, but termination of the arrhythmia is uncommon. Verapamil may prolong episodes of AF through a proarrhythmic effect
- *MAT*[31]*:* calcium channel blockers are effective
- *SVT following cardiac surgery:* diltiazem has been shown not only to reduce, but also to decrease incidence of ventricular arrhythmia and postoperative ischaemia
- *AF associated with the WPW syndrome:* calcium channel blockers may increase the ventricular response and should be avoided if this is suspected.[28]

In general, calcium channel blockers should not be given to patients with a wide-complex tachycardia not only because of the risk of accelerating accessory pathway conduction, but also because their myocardial depressant effects can result in cardiovascular collapse in the setting of VT and pre-existing myocardial dysfunction.

VERAPAMIL

Verapamil is cleared by the liver with an elimination half-life of 3–8 h. Therapeutic plasma concentration is 0.1–0.15 mg/L. With the availability of adenosine and the better tolerance of diltiazem, the use of verapamil has fallen substantially:

- *Loading dose i.v.:* 1 mg/min to a maximum of 10–15 mg or 0.15 mg/kg
- *Maintenance dose i.v.:* 5 mg/kg per min
- *Maintenance dose oral:* 80–120 mg 6–8-hourly.

DILTIAZEM

Diltiazem is cleared by the liver with an elimination half-life of 3.5 hours. There is reduced oral absorption and extensive first-pass hepatic metabolism: only 40% of oral dose is available compared with i.v.:

- *Loading dose i.v.:* 0.25 mg/kg, followed by 0.35 mg/kg if required
- *Maintenance dose i.v.:* 5–15 mg per hour
- *Maintenance dose oral:* 60–120 mg 6–8-hourly
- *SVT prophylaxis following cardiac surgery:* 0.1 mg/kg per hour, starting at onset of bypass and continuing for 24 hours. The dose can be titrated up for blood pressure control.

MAGNESIUM

Magnesium is an emerging antiarrhythmic agent with a range of indications; however, as an antiarrhythmic agent, magnesium has largely defied classification. Magnesium has many reported electrophysiological effects, including blocking voltage-dependent L-type Ca^{2+} channels. Magnesium is a necessary cofactor for the membrane enzyme Na^+/K^+-ATPase that provides energy for the membrane Na/K channels.[96] Consequences of magnesium deficiency are as follows:

- Intracellular potassium falls and intracellular sodium rises, leading to a reduction in RMP.
- Intracellular sodium is elevated, increasing the availability of sodium for the Na/Ca counter transport mechanism.
- The resulting elevation in intracellular calcium predisposes to DAD-triggered activity.

Magnesium administration reduces the availability of intracellular Na^+ and therefore this Ca^{2+} inward current. The dependency of normal membrane potassium gradients on magnesium is demonstrated by the inability to correct intracellular potassium deficiency with the administration of potassium in the setting of hypomagnesaemia. The antiarrhythmic properties of supra-normal levels of magnesium associated with pharmacological doses of magnesium appear to be largely due to augmentation of this physiological role of magnesium. Therefore, magnesium may be best classified as a Na/K pump agonist.

Magnesium in pharmacological doses decreases RMP, resulting in a reduction in automaticity. However, once depolarisation occurs, the maximum rate of depolarisation and action potential amplitude is increased, thereby improving conduction. Action potential duration is increased, thereby increasing the absolute refractory

period and reducing relative refractory period. The net result is a reduction in the vulnerable period and more synchronous conduction. All of these electrophysiological effects are augmented in the setting of increased extracellular potassium. It is not surprising that the utility of magnesium appears greatest in the setting of ischaemia where loss of potassium from the cell is a major consequence. A secondary effect is the reduction in the availability of intracellular sodium to contribute to inward calcium flux, producing triggered activity. Magnesium has also been shown to elevate VF and ectopy threshold.[97]

INDICATIONS

- Acute rate control of AF, and has been shown to be as effective as amiodarone in the short term[69]
- Prevent postoperative SVT following cardiac surgery with varying efficacy
- Acute control of MAT
- Ventricular arrhythmia associated with triggered activity, such as torsade de pointes and digoxin toxicity[90]
- Drug-induced polymorphous VT, particularly that caused by class I agents, can also be terminated with magnesium
- Appears very effective at controlling transient ventricular arrhythmia in the setting of ischaemia such as post-infarct and cardiac surgery.

DOSE

- *AF rate and MAT control:* 0.15 mmol/kg as slow i.v. push. Subsequent dose recommendation has varied from 60 mmol to 0.1 mmol/kg per hour for 24 hours. Magnesium levels following 0.1 mmol/kg per hour were 1.92±0.49 mmol/L at 24 hours
- *SVT prophylaxis following cardiac surgery:* 20–25 mmol per day for 4 days
- *Transient ventricular arrhythmia:* 10 mmol as a slow i.v. push, repeated if required
- *LIMIT-2 post myocardial infarction dose:* 8 mmol bolus over 5 min, followed by 65 mmol over 24 hours. Mean plasma level 1.55 (SD 0.44) mmol/L.[71]

PLASMA LEVELS

Observational data would suggest that plasma levels of magnesium required for potent antiarrhythmic action are at least 1.8 mmol/L.

ADVERSE EFFECTS

- When administered too rapidly, magnesium can cause hypotension by excessive peripheral vasodilatation; this is associated with an unpleasant hot-flush sensation.
- Prolonged administration or excessive dosing can produce plasma levels associated with skeletal muscle weakness, which can be clinically significant in acute-on-chronic respiratory failure.
- Excessive action can be seen if magnesium is used in the setting of hyperkalaemia, resulting in bradyarrhythmia and heart block.

PROCAINAMIDE

Procainamide is a class IA antiarrhythmic drug with potent Na^+ channel-blocking activity and intermediate K^+ channel-blocking activity. The Na^+ channel-blocking action has an intermediate time constant of recovery. Procainamide has similar electrophysiological and ECG effects to quinidine but lacks vagolytic and alpha-adrenergic blocking activity:

- decreases automaticity
- increases refractory period
- slows conduction.

Procainamide is metabolised to *N*-acetyl procainamide. *N*-acetyl procainamide lacks Na^+ channel-blocking activity, but is equipotent in K^+ channel blockade and prolongation of action potential. The increasing effect of greater refractoriness and QT prolongation with chronic procainamide therapy relates to increased contribution of *N*-acetyl procainamide.

CLINICAL USE

Procainamide is used to treat both atrial and ventricular arrhythmias.

- Intravenous procainamide is more effective than lidocaine for terminating VT.
- Procainamide controls ventricular rate in AF and Afl.
- It is effective for conversion of AVNRT, AVRT and possibly AF and Afl.
- It controls rapid ventricular rate owing to accessory pathway conduction in pre-excitation syndromes and for wide-complex tachycardia that cannot be distinguished as being SVT or VT.

The need to infuse slowly to avoid hypotension is the major barrier to wider use in life-threatening arrhythmia. Maintenance therapy with procainamide is not widely used due to its side-effect profile:

- *Loading dose i.v.:* 6–17 mg/kg at 20 mg/min until there is arrhythmia control, hypotension ensues or QRS duration increases by more than 50%. Up to 50 mg/min has been used in urgent situations
- *Maintenance dose i.v:* 1–4 mg/min
- *Plasma levels: N*-acetyl procainamide has a longer duration of action
- *Adverse effects:* as with quinidine, the ventricular response may be accelerated if given for SVT; QT-interval prolongation and torsade de pointes may also occur.

A reversible lupus-like syndrome develops in 20–30% of patients receiving procainamide long term. Other side-effects include gastrointestinal disturbances (less

common than with quinidine), central nervous system manifestations and cardiac depression.

LIDOCAINE

Lidocaine, long considered an important antiarrhythmic drug for ventricular tachyarrhythmia, is now relegated to lower-choice options or missing from most treatment algorithms. Na^+ channel-blocking effect is increased in myocardial ischaemia and is unproven outside acute ischaemia settings. It has no effect on SA node automaticity, but it depresses automaticity in other pacemaker tissues. Normally, lidocaine has little or no effect on conduction. The ECG shows no changes in sinus rate, PR interval, QRS width or QT interval with lidocaine.

CLINICAL USE

Lidocaine has reducing importance.

- It is ineffective against SVT.
- Amiodarone has taken over as the antiarrhythmic of choice for DC shock-resistant VF.[63,64]
- Lidocaine increases the current required for defibrillation, increases the likelihood of post DC shock asystole and therefore is detrimental during an episode of VF.
- Prophylaxis to prevent VF in AMI can no longer be recommended.

Extensive first-pass hepatic metabolism precludes oral use of lidocaine; i.v. dose should be reduced by 30–50% in severe liver disease or heart failure. The distribution half-life is about 8 min, and the elimination half-life is 1.5 h in normal patients (but may be increased >10 hours in severe heart failure or shock). An initial bolus of i.v. lidocaine 1.5–2.0 mg/kg over 1–2 min, followed by an infusion of 4 mg/min for 1 hours, then 2 mg/min for 2 hours, and thereafter 1–2 mg/min, is recommended. Increasing the maintenance infusion rate without an additional bolus requires about 6 hours (four elimination half-lives) to reach a steady state. If the initial bolus is ineffective, another bolus of 1 mg/kg may be given after 5 min. Another dosage regimen is 1.5–2.0 mg/kg initially, and 0.8 mg/kg at 8-minute intervals for three doses (i.e. three distribution half-lives), and thereafter 1–2 mg/min by infusion. The half-life of lidocaine increases after 24–48 hours as the drug in effect inhibits its own hepatic metabolism and dose reduction is required.

ADVERSE EFFECTS

Central nervous system toxicity with high plasma concentrations is the most common adverse effect (e.g. dizziness, paraesthesia, confusion, and coma and convulsions). Uncommonly, AV block or cardiac depression may occur. Cimetidine reduces lidocaine clearance, potentially causing toxic drug concentrations.

FLECAINIDE

Flecainide exhibits rate-dependent Na^+ channel blockade with slow time constant of recovery, with marked slowing of conduction in all cardiac tissue, and little prolongation of refractoriness.

CLINICAL USE

- May revert AVNRT and AVRT, although adenosine and verapamil are more widely used
- Useful in SVT, including AF and possibly Afl, particularly in the setting of accessory pathway syndromes
- Flecainide has been given in life-threatening VT.

Flecainide can be administered i.v. or orally. If flecainide is deemed necessary for prophylaxis of ventricular arrhythmias, therapy should start with ECG monitoring. In CAST, suppression of VEBs after myocardial infarction with flecainide was associated with increased mortality:[15]

- *Dose:* i.v. loading 2 mg/kg at 10 mg/min
- *Oral maintenance:* 100–200 mg 12-hourly.

ADVERSE EFFECTS

- Depression of cardiac contractility – flecainide is usually contraindicated in patients with abnormal LV function as it can worsen or precipitate heart failure.
- Conduction block – avoid in high-degree AV block unless a pacemaker is in situ.
- Flecainide increases pacing capture threshold.
- Proarrhythmic events are common, especially in patients with depressed LV function, and may be life-threatening.
- Torsade de pointes may occur, even in patients without structural heart disease.
- Incessant VT may be induced, unresponsive to any therapy, including cardioversion.
- Although flecainide depresses intracardiac conduction, a paradoxical increase in ventricular rate may occur with Afl or AF.
- Central nervous system effects include visual disturbances, dizziness and nausea.

PROPAFENONE

Propafenone is a class IC agent and has a structure similar to flecainide. The electrophysiological, haemodynamic and side-effect profile is also similar to flecainide and encainide. The I_{Na} blocking profile of propafenone has a fast time-constant resulting in greater activity at faster rates and less risk of bradycardia. In addition, propafenone has non-selective beta-blocking properties and can produce bronchoconstriction. Similar to flecainide, propafenone could be considered in both ventricular and SVT arrhythmia in the setting of normal LV function. Use of long-term

propafenone should probably be limited because of its class IC profile, even though it was not included in the CAST study and contraindicated in structural heart disease because of proarrhythmia.

Propafenone is metabolised by the liver and the rate can vary significantly between patients. The short terminal half-life requires at least t.d.s. administration.

- *Dose:* i.v. 2 mg/kg at 10 mg/min; oral starting at 450–900 mg/day decreasing to 300 mg/day in three divided doses.

AMIODARONE

Amiodarone is a potent antiarrhythmic agent with a complex electrophysiological and pharmacological profile. The appealing broad spectrum and haemodynamic stability of amiodarone have resulted in it emerging as the most frequently used antiarrhythmic in critically ill patients. In this setting short-term use predominates and the formidable side-effect profile is much less significant. Amiodarone:

- prolongs action potential duration
- increases the refractoriness of all cardiac tissue
- has Na^+ channel blockade (class I), antiadrenergic (class II), calcium channel blockade (class IV) and antifibrillatory effects. The Na^+ channel blockade of amiodarone has a fast time constant for recovery
- QT prolongation reflects a global prolongation of repolarisation and is closely associated with its antiarrhythmic effects.

When given i.v., amiodarone has little immediate class III effect: the major action is on the AV node, causing a delay in intranodal conduction and a prolongation of refractoriness. This probably explains why i.v. amiodarone controls the ventricular rate in recent-onset AF, but is less effective for termination of this arrhythmia. Administration i.v. causes some cardiac depression, the magnitude depending on rate of administration and pre-existing LV function. Cardiac index is often unchanged because of its vasodilator properties.

CLINICAL USE

It is effective in suppressing both supraventricular and ventricular tachyarrhythmia.

SUPRAVENTRICULAR TACHYCARDIA

Amiodarone is effective in terminating and suppressing recurrences of AVNRT and AVRT tachycardia, although adenosine (for acute reversion) or verapamil (acute termination and long-term prophylaxis) is superior. Amiodarone i.v. is less effective in reverting Afl or AF, but the ventricular rate will slow. Administration over a longer time span (days to weeks) may be more effective in reverting recent-onset AF. In preventing recurrence of AF after reversion, amiodarone is comparable in efficacy to quinidine and flecainide but superior to sotalol and propafenone.[48]

DOSE

- Lower doses than that required for ventricular arrhythmia are usually sufficient
- *AVNRT and AVRT reversion or AF and Afl rate control:* 3–5 mg/kg i.v. over 10–60 min depending on blood pressure and myocardial function, followed by 0.35–0.5 mg/kg per hour. Poor rate control can be improved with additional 1–2 mg/kg boluses
- *Postoperative AF prophylaxis:* 200 mg orally 8-hourly for 5 days, followed by daily until hospital discharge
- *Long-term SVT control or AF rate control:* 100–200 mg/day orally will usually suffice.

VENTRICULAR TACHYARRHYTHMIAS

Amiodarone i.v. may be effective in treating life-threatening ventricular tachyarrhythmia refractory to other drugs, especially in myocardial infarction and poor LV function. Amiodarone's efficacy in DC shock-resistant VF further confirms a prominent role in this setting.[63,64] Long-term oral amiodarone is useful in controlling symptomatic VT and VF, especially when other conventional antiarrhythmics have failed. The absence of negative inotropic effect is useful in those with severely depressed LV function, but its many adverse effects limit widespread use. The Cardiac Arrest in Seattle, Conventional versus Amiodarone Drug Evaluation (CASCADE) study demonstrated that empirical amiodarone treatment was superior to guided (non-invasive Holter or EPS) class I drugs in survivors of VF not associated with AMI. Amiodarone prevented arrhythmia recurrence and decreased the incidence of sudden death. Amiodarone, presumably because it is better tolerated in patients with poor LV function and having less proarrhythmia, can be considered as first-line drug to prevent life-threatening ventricular tachyarrhythmias.[77–79] The rate of arrhythmia control is often slower with ventricular arrhythmia and may take several days to achieve. This delay appears to be independent of dose. The pharmacodynamic basis for this relates to the fact that much of the class III or K^+ channel-blocking activity is due to the amiodarone metabolite, desethylamiodarone, whereas the predominant actions of acute administration of amiodarone are due to its class I and class II activity. The full potency of the class III activity requires several days, at least, for the effects of desethylamiodarone to appear.

DOSE

- *Haemodynamic stable VT:* 5–7 mg/kg over 30–60 min, followed by 0.5–0.6 mg/kg per hour
- *DC shock-resistant VF:* 5 mg/kg, followed by 2.5 mg/kg if required[64]
- *Long-term prevention of ventricular arrhythmia:* oral loading with 1200 mg/day for 1–2 weeks, reducing to 400–600 mg/day and then 100–400 mg/day after 2–3 months. The dose should probably not be

reduced below 400 mg/day with life-threatening ventricular arrhythmia.

MYOCARDIAL INFARCTION

Data are limited at present, but amiodarone may improve long-term survival in patients after myocardial infarction.

PHARMACOKINETICS

Oral bioavailability of amiodarone is variable at 40–70%, with a delayed onset of action (days to weeks); however loading doses reduce this interval. Initial i.v. dose recommendations were 5–7 mg/kg over 30 min, followed by 50 mg/h. The kinetics of amiodarone has been modelled to four compartments when given acutely. Following a slow i.v. bolus over 15 min, amiodarone is rapidly distributed to the active compartment ($t_{1/2}\alpha$=4.2 min), with demonstrable prolongation of QTc and antiarrhythmic effect within 2–5 min. Subsequently, amiodarone is progressively redistributed to 'deeper' compartments ($t_{1/2}\beta$=36.6 min, $t_{1/2}\,\gamma$=4.5 h and $t_{1/2}\delta$=33.6 h).[98] This is in contrast to the very prolonged terminal half-life – greater than 50 days – after long-term treatment. This redistribution of amiodarone explains why repeated boluses are often required in the first 24–48 hours of treatment. Transient loading-dose hypotension due to myocardial depression or vasodilatation is dose-, rate- and patient-dependent. A loading dose of 5 mg/kg over 20 min resulted in significant further myocardial depression and a fall in cardiac index, whereas in patients without evidence of heart failure, 5 mg/kg over 1 minute resulted in hypotension due to systemic vasodilatation and an increase in cardiac index.[99,100]

MONITORING

Plasma amiodarone concentrations have poor correlation with arrhythmia control, and therapeutic levels, 1.0–2.5 mg/L, have the greatest utility for avoidance of adverse effects in long-term treatment.

ADVERSE EFFECTS

Adverse effects will occur in the majority of patients if they receive amiodarone for long enough. Most are reversible when the drug is discontinued. Adverse effects include:

- *Dermatological:* photosensitivity, bluish/grey skin discoloration (slate-blue skin)
- *Eye:* corneal microdeposits (almost 100%) with little or no clinical significance
- *Gastrointestinal disturbances*
- *Hypo- and hyperthyroidism*
- *Liver dysfunction:* asymptomatic increases in liver enzymes are common, and do not require amiodarone cessation unless enzymes are 2–3 times normal; hepatitis is rare
- *Neuropathy, myopathy and cerebellar abnormalities*
- *Pulmonary toxicity:* unexpected acute respiratory distress syndrome has been reported in patients on amiodarone undergoing procedures such as uncomplicated cardiopulmonary bypass surgery and pulmonary angiography. These observations suggest that amiodarone may predispose the lung to acute injury. Pulmonary toxicity is the most serious adverse effect, with a reported incidence of 10% at 3 years. Amiodarone pulmonary toxicity has been reported in one case after 13 days and 11.2 g cumulative dose and 11.2 g over 2 weeks in another. Patients on long-term amiodarone need regular respiratory function testing and decreased carbon monoxide diffusion of 15% below baseline requires dose modification or cessation. The severe syndrome of shortness of breath, cough and fever with pulmonary crepitations and widespread pulmonary infiltrates on chest X-ray has a mortality of 10%. Immediate discontinuation is necessary. Use of steroids is controversial.

Amiodarone interacts with other drugs, potentiating warfarin, digoxin and other antiarrhythmic agents. When administered concurrently, doses of these drugs should be reduced accordingly. On the positive side, long-term amiodarone is unlikely to precipitate or worsen heart failure and proarrhythmia is uncommon.

DRONEDARONE[49,101]

Dronedarone is an amiodarone analogue designed to reduce the lipophilicity of the molecule to reduce the pharmacokinetic complexity and toxicity. The iodine moieties have also been eliminated to prevent thyroid dysfunction.

Dronedarone is a multi-channel blocker, blocking I_{Na}, I_K and $I_{Ca\text{-}L}$ channels with a predominant electrophysiological effect of prolonging repolarisation or class III. It also has antiadrenergic properties.

Dronedarone decreases the recurrence of AF, controls rate with recurrences (heart reduction of 12.3 beats/min compared with placebo), especially with exercise. Secquential major studies evaluating dronedarone highlight the importance of variable outcome in differing patient populations. In comparing dronedarone with placebo the ATHENA study found dronedarone reduced all-cause mortality, cardiovascular admissions by 24%, death from cardiac arrhythmias, HR 0.55 (0.34–0.88) and stroke rate in addition to delaying recurrence of AF/Afl. Whereas in the PALLAS study (patients with permanent AF) all these outcomes were worse and the ANDROMEDA study (patients with poor LV function) was stopped due to increased mortality due to worsening heart failure. Meta-analysis of all placebo-controlled trials does show dronedarone has reduced mortality, but maintenance of sinus rhythm and absence of LV dysfunction is important to confer this mortality benefit. Dronedarone is currently contraindicated in patients with NYHA class III or IV heart failure.

In comparing dronedarone to amiodarone the picture is even less clear. In the DIONYSOS study (post electrical cardioversion) there was increased AF recurrence, dronedarone 63.5% and amiodarone 42% at 7 months, although drug discontinuation was higher with amiodarone. Meta-analysis of studies comparing the two drugs confirms greater efficacy for amiodarone maintaining sinus rhythm (HR 0.49; 0.37–0.63) but greater drug discontinuation rates and a trend to increased all-cause mortality with amiodarone. Dronedarone may have reduced torsade de pointes arrhythmia. The increased efficacy of amiodarone may relate to its lipophilicity giving higher tissue levels or the increased activity of its major metabolite, desethylamiodarone compared with *N*-debutyldronedarone.

Dronedarone has poor oral bioavailability, 15%, which can be variable, increasing by a factor of three if taken with food. It is extensively metabolised by cytochrome P450 CYP3A4 (inhibitors can result in marked elevation in plasma levels) to the metabolite *N*-debutyldronedarone, which is much less potent. The elimination half-life is 24 hours. Serum digoxin levels are increased due to inhibition of P-glycoprotein mediated intestinal and renal excretion.

- *Dose:* 400 mg oral b.d. with steady state in 7 days.

Although long-term data are lacking, there has been no evidence of thyroid dysfunction or pulmonary toxicity.

SOTALOL

Sotalol prolongs action potential duration, thereby prolonging the effective refractory period in the atria, ventricles, AV node and accessory AV pathways. It is also a potent non-cardio-selective beta-adrenergic blocker (class II). Sotalol also has antifibrillatory actions that are superior to those of conventional beta blockers. It can worsen heart failure in patients with depressed LV function. The negative inotropic beta-blocking effect is slightly offset by a weak positive inotropic effect owing to prolongation of the action potential (resulting in more time for calcium influx into contracting myocardial cells).

CLINICAL USE

Higher doses of sotalol are required to prolong cardiac repolarisation than to cause beta blockade. Sotalol may be administered i.v. or orally, and is excreted by the kidneys (elimination half-life 15 hours); i.v. dose is 0.5–1.5 mg/kg over 5–20 min. Oral therapy is initiated at 80 mg 12-hourly and increased to 160 mg 12-hourly, although doses of 320 mg 12-hourly have been administered.

SUPRAVENTRICULAR TACHYCARDIA

- Effective in AVNRT and AVRT, although adenosine and verapamil are superior. Long-term sotalol will prevent recurrences of these arrhythmias
- Probably ineffective for reversion of AF/Afl, but is effective in preventing recurrence of AF after cardioversion. If AF recurs, heart rate is likely to be well controlled with sotalol
- Prevents postoperative SVT.

VENTRICULAR ARRHYTHMIAS

Sotalol is superior to lidocaine to terminate sustained VT, and should be considered a first-line drug in patients without heart failure. Oral sotalol is more effective than class I drugs for the long-term prevention of VT or VF. Guided (Holter or EPS) sotalol and empirical amiodarone are first-line drugs to prevent recurrences of VT and VF over the long term; however, the worse outcome with sotalol in SWORD has significantly reduced the role of sotalol in this setting.[76]

ADVERSE EFFECTS

Side effects of sotalol are mainly due to beta blockade (e.g. bronchospasm, heart failure or AV conduction problems) and prolongation of QT proarrhythmia (e.g. torsade de pointes, similar 2% incidence as quinidine, which may occur early during drug titration or later during long-term treatment).

IBUTILIDE

Ibutilide is an I_{Kr} K^+ channel blocker, which prolongs action potential and increases the refractory period. This agent, with class III effect, is recommended for acute pharmacological conversion of AF and Afl, or as an adjunct to improve success of DC shock cardioversion. The success rate for ibutilide alone is higher for Afl (50–70%) than that with AF (30–50%) and, as expected, efficacy is greatest in short-term AF/Afl without structural heart disease. The major role of ibutilide appears to be cardioversion pretreatment to facilitate reversion to sinus rhythm from AF.[46] Ibutilide has minimal effect on blood pressure and heart rate and the major adverse effect is proarrhythmia, with torsade de pointes occurring in 3–6% of patients. For this reason, patients should be monitored for at least 6 h after administration. Ibutilide has a short duration of action and other antiarrhythmic drugs are required to maintain sinus rhythm.

DOSE

For patients weighing more than 60 kg, 1 mg over 10 min, which can be repeated 10 min later if unsuccessful. In patients weighing less than 60 kg, 0.01 mg/kg is given as initial dose.

DOFETILIDE

Dofetilide is one of the latest class III I_{Kr} K^+ channel blockers being investigated in the hope of finding an antiarrhythmic drug for long-term use with amiodarone's efficacy but without its side-effect profile.

Dofetilide's emerging role is again in pharmacological cardioversion of AF and Afl (superior to sotalol, similar to amiodarone but inferior to ibutilide) in about 30% of patients. Prevention of recurrence is similar to amiodarone and long-term oral therapy is not associated with increased mortality in post-MI and heart failure patients. It also appears safe in patients with LV dysfunction. Early (first 3 days) proarrhythmia (3.3% of patients developed torsade de pointes) also necessitates monitoring with commencement of therapy.[43,47,102,103]

DOSE

Recommended dose is 500 mg orally 12-hourly. Dose requires adjustment for renal function and QT-interval monitoring (QT_c interval >500 ms necessitates cessation) for a minimum of 3 days.

VERNAKALANT[104]

Vernakalant, a pyrrolidine compound, is a new multichannel blocker with I_K- and I_{Na}-blocking activity, with I_K blockade predominating (class III agent). The unique profile of vernakalant I_K blockade is the relative specificity for the atria and minimal effect on the ventricle. This specificity relates to differential activity on the various I_K channel isoforms, with I_{Kur} blockade being much greater compared with the modest activity at I_{Kr} channels. I_{Kur} channels are the 'ultra-rapid' I_K channels confined to the atria that are responsible for the fast early phase of repolarisation that results in the shorter action potential of atrial cells. Vernakalant therefore specifically prolongs atrial refractory period and slows atrial conduction with a rate-dependent profile.

Vernakalant in non-surgical, short-duration AF (ACT I and ACT III studies, duration less than 7 days) achieved sinus rhythm in 51.7% and 51.2% (placebo 4 and 3.6%) within 90 minutes, generally less than 10 minutes (median time to conversion 10 and 11 minutes). The i.v. dose of 3 mg/kg over 10 minutes, followed by a further 2 mg/kg over 10 minutes if conversion did not occur within 15 minutes of the first dose, produced not only rapid but durable conversion with 99% of responders remaining in sinus rhythm at 24 hours. Vernakalant was not effective in Afl, with a conversion rate of only 7%.

A similar cohort (AVRO study) comparing vernakalant (same dose as ACT I and III) with amiodarone (5 mg/kg over 1 hour followed by 50 mg over the next hour), again in recent-onset AF, found vernakalant again superior at 90 minutes with a conversion rate of 51.7 versus 5.2%. However at 4 hours amiodarone was catching up with 22.6 versus 54.4% conversion, with amiodarone recognised to have a longer onset of action.

In post-cardiac surgical patients who developed AF, having been in sinus rhythm preoperatively (ACT II study), vernakalant was superior to placebo with rapid conversion rates (47 versus 14%) and times (median time 12.4 minutes). However, unlike non-surgical patients, in this cohort responders were less durable with only 60% remaining in sinus rhythm at 24 hours. In all studies vernakalant had no effect on success rates with subsequent attempts at electrical cardioversion.

Vernakalant is extensively metabolised by the liver and subsequently excreted in the urine. The acute kinetics of vernakalant is not affected by congestive cardiac failure, renal or hepatic impairment.

Vernakalant is well tolerated with serious side-effects of hypotension and bradycardia during infusion infrequent (7.6%, placebo 5.1%), slightly higher than the rates of hypotension with amiodarone.

Although vernakalant may be seen as agent of choice for rapid pharmacological conversion of recent onset of AF, <7 days (the greater efficacy of ibutilide is eroded by risk of polymorphous ventricular arrhythmia), the superior conversion rate over amiodarone would appear to be lost at 24 hours and beyond, with amiodarone also likely to be a better agent to control ventricular rate in non-responders with greater AV-blocking activity.

ADENOSINE

Adenosine stimulates specific A_1 receptors present on the surface of cardiac cells, thereby influencing adenosine-sensitive K^+ channel cyclic adenosine monophosphate production. It slows the sinus rate and prolongs AV node conduction, usually causing transient high-degree AV block. The half-life of adenosine is usually less than 2 min as it is taken up by red blood cells and deaminated in the plasma. This ultrashort half-life is a major advantage over other antiarrhythmic drugs. The effects of adenosine, both antiarrhythmic and haemodynamic, can be antagonised by methylxanthines, especially theophylline and caffeine. Dipyridamole, an adenosine uptake blocker, potentiates the effect of adenosine. Adenosine effects are prolonged in patients on carbamazepine and in denervated transplanted hearts.

CLINICAL USE

- *AVNRT and AVRT tachycardia:* adenosine is the drug of choice. Expected reversion rates exceed 90%.[26] The AV nodal-blocking actions of adenosine may unmask atrial activity (e.g. flutter waves in Afl).
- Diagnosis of a wide-complex tachycardia may be assisted by the use of adenosine.
- SVT with intraventricular conduction block will terminate with adenosine, whereas few VTs will revert. Whether adenosine should be used routinely to discriminate between VT and SVT with aberrant conduction in haemodynamically stable wide-complex tachycardia is unclear. Potential for haemodynamic collapse in VT is real and ILCOR advises against.

Adenosine will not revert AF. Ventricular rate may transiently increase when AF is associated with the WPW syndrome.

Adenosine is given as a rapid bolus through a large peripheral or central vein followed by a saline flush, at

intervals less than 60 seconds. The usual dose is 6 mg, followed by 12 mg if response is ineffective. Another 18 mg can be given if the last dose was well tolerated.

ADVERSE EFFECTS

Most patients experience transient side-effects such as flushing, shortness of breath and chest discomfort. Adenosine should not be given to asthmatic patients as bronchospasm may result.

DIRECT CURRENT CARDIOVERSION

DC cardioversion/defibrillation is an important treatment option in tachyarrhythmia. In addition to its emergency role in cardiac arrest from VF or VT, urgent DC cardioversion is indicated in haemodynamically unstable VT and sustained SVT that precipitate angina, heart failure or hypotension. More elective DC cardioversion is indicated in haemodynamically stable VT following a trial of antiarrhythmic drug therapy. Cardioversion is most commonly used in AF/Afl once potential precipitants have been eliminated and, again, usually after antiarrhythmic drug treatment to prevent further episodes. Digoxin toxicity is a relative contraindication to DC cardioversion, which should also be used with care in patients on digoxin.

MECHANISM OF ACTION

DC shocks need to produce a current density that depolarises a critical mass of myocardium, thereby leaving insufficient myocardium to maintain the re-entrant tachycardia and prevent recurrence. For VF and AF, the critical mass involves the entire ventricles or atria, whereas for the more organised tachyarrhythmia, VT and Afl, which involve specific re-entrant circuits, regional depolarisation in the path of their circulating wave fronts is all that is required. DC shocks also prolong the refractoriness of myocardium and this effect will contribute to the arrhythmia termination and prevention of immediate recurrence.

ELECTRICAL ENERGY

Even though the goal is to achieve a certain current through the entire heart, atria or a region depending on the arrhythmia, DC shocks are prescribed as energy measured in joules (J) or watt-seconds. Obviously it would make more sense to be able to deliver a set current. This would prevent delivering inappropriately low currents in patients with high impedance and excessive current flow causing myocardial damage in patients with low impedance. Clinical studies to determine current doses are under way for defibrillation and cardioversion. The optimal current for VF using monophasic damped sinusoidal (MDS) waveform for cardioversion waveform appears to be 30–40 A. Current dosage for biphasic waveform is not available.

CURRENT WAVEFORM

Modern defibrillators deliver a current, the magnitude of which depends on the prescribed energy and thoracic impedance. This current can be delivered in a number of different waveforms.

MDS defibrillators deliver current that is in a single direction or polarity. They can be further characterised by the rate at which the current pulse returns to zero. MDS waveforms return to zero gradually, whereas truncated exponential waveforms return instantaneously. Recent evidence suggests that biphasic waveform for cardioversion (BTE) provides equal efficacy at lower electrical energies. A sequence of two current pulses is generated; the polarity of the second is in the direction opposite to the first. Biphasic waveforms with lower shock energies are associated with fewer ST-segment changes and less post-resuscitation myocardial dysfunction and have an ILCOR class IIa recommendation.

THORACIC IMPEDANCE

The magnitude of current flow is dependent on the resistance to current flow or thoracic impedance. The average adult thoracic impedance is 70–80 Ω. Factors that determine thoracic impedance include:

- energy selection
- electrode size
- electrode composition
- paddle-to-skin coupling
- distance between electrodes
- number of previous shocks
- time interval between previous and present shock
- pressure on electrodes
- phase of ventilation
- patient's body build
- recent sternotomy.

Conductive gel reduces impedance, while hair trapping air between skin and paddle and self-adhesive monitor/defibrillator electrode pads may increase it. There is no clear relationship between body size and energy requirements but compensation for patient-to-patient differences in impedance can be achieved by changes in duration and voltage of shocks, or by a process called burping, which involves releasing the residual membrane charge.

PADDLE POSITION AND SIZE

ILCOR recommends standard placement of the sternum paddle just to the right of the upper sternal border below the clavicle and the apex paddle to the left of the nipple, with the centre of the paddle in the mid-axillary line. Permanent pacemakers and ICD must be avoided as shock may cause malfunction or block current going to the heart. Inevitably, some current passes down the pacemaker lead and it is necessary to check pacing threshold post-shock. Other alternative paddle

placements can enable avoidance of pacemakers and ICD or perhaps improve current direction. Using self-adhesive electrodes, the sternum electrode can be placed posterior to the heart on the right infrascapular region and the apex on the left precordium. The use of right parasternal and left posterior infrascapula has been advocated for AF because this configuration provides an optimal vector of current delivery to the atria. Large electrodes or paddles have less impedance; however, excessively large electrodes may result in less transmyocardial current flow. The minimum recommended electrode size is 50 cm^2, with the sum of both electrodes exceeding 150 cm^2.

SYNCHRONISED CARDIOVERSION

With cardioversion of atrial tachyarrhythmia and VT, when time permits, synchronisation of DC shock with the R-wave of the QRS complex is required to reduce the possibility of inducing VF by delivering the shock during the relatively refractory portion of the T-wave of the cardiac cycle. Synchronisation in VT may be difficult and misleading because of the wide complex or polymorphous nature. Synchronisation should not delay DC shock in pulseless VT or VT associated with unconsciousness, hypotension or severe pulmonary oedema.

DIRECT CURRENT SHOCK DOSAGE

Recommendations for energy doses are changing, as biphasic waveform generators become more widely available. Where studied, BTE shocks have been consistently as effective as higher-energy MDS shocks. Recommended doses are always a balance between the energy likely to generate a critical current flow and that not likely to cause functional and morphological damage. Electrical energies greater than 400 J have been reported to cause myocardial necrosis.

- *VF and pulseless VT:* escalating MDS shocks, starting at 200 J, then 200–300 J and, finally, 360 J. Evidence for sequential escalation of the energy dose is not strong and repeated shocks at the same energy result in increasing current delivery as impedance falls. Repeated non-escalating lower-energy BTE shocks, in the range of 150–175 J, are as effective as escalating MDS recommendations.
- *VT:* energy dose for cardioversion of VT depends on morphology and rate. For monomorphic VT, synchronised 100 J MDS is the starting energy. For polymorphic VT, synchronised if possible, 200 J MDS is the starting energy and for both stepwise increases if the first shock fails.
- *AF:* initial energy is synchronised 100–200 J MDS and stepwise increases if first shock fails. Despite obvious concerns for myocardial injury, mega dose energy at 720 J has been used with success in large patients with AF refractory to 360 J, without evidence of myocardial injury. Constant-current, rectilinear biphasic waveforms appear to be more effective in cardioverting AF. This biphasic waveform at the low energy of 120 J was superior to 200 J MDS.
- *Afl, AVNRT and AVRT:* these atrial tachyarrhythmias require least energy and the initial recommended energy is synchronised 50–100 J MDS.

SEDATION

A separate doctor expert in managing the airway must perform sedation for cardioversion. The dose of the sedating agent is titrated on the basis of patient factors and type of arrhythmia. Patients with poor myocardial function not only need reduced dose, but also onset time is slower because of low cardiac output. Sensitive tachyarrhythmias such as Afl require only low doses, whereas AF is likely to need higher and repeated doses as higher energy and repeated shocks may be necessary. Cardioversions should be performed with standard resuscitation equipment available and pre-oxygenation is crucial.

DIGOXIN AND CARDIOVERSION

Digoxin toxicity results in a significant reduction in the threshold for inducing ventricular arrhythmia with DC shock. If digoxin toxicity is a possibility, then reconsideration of the need for cardioversion or at least careful titration of energy is required. Clinical experience would suggest the latter procedure of starting with 10 J MDS, and a stepwise increase thereafter increases safety of DC shock in this setting.

ANTICOAGULATION FOR CARDIOVERSION[105]

Cardioversion of AF and, to a lesser extent, Afl is associated with catastrophic thromboembolism, especially stroke. Early studies suggested an incidence of up to 6.3% without anticoagulation. It is accepted that the likelihood of clots forming in the left atrium after 48 hours in AF and for these to be dislodged when sinus rhythm is restored is so high that anticoagulation is indicated prior to cardioversion in AF.

Anticoagulation for 3–4 weeks before cardioversion reduced the risk of embolism by 80%. The risk of thromboembolism following cardioversion continues for a period.

- Echocardiographic findings suggestive of atrial thrombi formation occur in up to 35% of patients post cardioversion.
- Left atrial appendage emptying velocities often decrease despite the development of coordinated electrical activity after cardioversion, presumably because of stunning of mechanical function.

Prolonged AF greater than 48 hours requires anticoagulation for 3 weeks prior to cardioversion and warfarin therapy for at least another 4 weeks depending on risk of recurrence of AF.

Transoesophageal echocardiography, which allows detection of thrombi in the left atrial appendage with much greater accuracy, has been found to be a safe means of expediting cardioversion. Anticoagulation with heparin for 1 day or warfarin for 5 days prior to demonstrating the left atrium to be free of thrombi by transoesophageal echocardiography, then 4 weeks of warfarin following cardioversion, was as effective in preventing emboli as the conventional longer anticoagulation regimen. However, there was a significant reduction in major haemorrhagic events in the transoesophageal echocardiography-guided, shorter lead-in anticoagulation strategy.

Cardiac pacing and implantable cardioverter defibrillators

Aaisha Opel and Oliver R Segal

Cardiac pacing has rapidly evolved since its introduction by Zoll in 1952.[1] The first pacemaker was an external device designed by John Hopps in 1950. This was followed by the insertion of an internal device in 1958 by Elmqvist and Senning. The technological knowledge gained in pacing has assisted in the even more rapidly advancing field of implantable cardioverter defibrillators (ICDs). Although implantation and follow-up of permanent pacemakers and ICDs are in the domain of appropriately trained cardiologists, intensive care physicians should be familiar with such devices as a significant number of critically ill patients will have cardiac rhythm devices. It is also essential, when urgent pacing is required, that the intensivist is skilled in aspects of temporary pacing, including lead insertion and testing.

Cardiac pacing repetitively delivers very low electrical energies to the heart, initiating and maintaining cardiac rhythm. Pacing may be temporary, with an external pulse generator, or permanent, with an implanted pulse generator. More recently, a hybrid approach has been developed using a standard permanent pacemaker generator and lead but externalising the generator outside the body. This is useful for patients needing long-term temporary pacing (e.g. those with systemic or device-related infection or those with long-term causes of temporary bradycardia such as Guillain–Barré syndrome or its variant Miller–Fisher syndrome). Pacing is usually used to treat bradycardia, but rapid atrial or ventricular pacing can also be used to terminate both supraventricular (SVT) and ventricular tachycardias (VT).

More recently, the indications for pacing have expanded beyond symptomatic bradycardia and include conditions such as the long QT syndrome, hypertrophic obstructive cardiomyopathy (HOCM) and congestive cardiac failure.

PACING SITES

TRANSVENOUS ENDOCARDIAL PLACEMENT

Pacing leads are passed via a vein to the endocardial surface of the right atrium (RA), the right ventricle (RV), or both chambers. In patients with heart failure, an additional lead is passed to the left ventricular coronary veins via the coronary sinus (which drains into the right atrium). Balloon-flotation pacing catheters for temporary pacing are less stable and are generally reserved for emergency pacing purposes.

EPICARDIAL PLACEMENT

This is mainly used in conjunction with cardiac surgery, where electrodes are attached directly to the epicardial surface of the atrium and/or ventricle and pass out through the skin in the epigastrium. These are useful after cardiac surgery, particularly after valve surgery, but rapidly deteriorate postoperatively and are typically no longer functional after 5–10 days.

TRANSCUTANEOUS EXTERNAL PACING

Transcutaneous pacing can be instigated rapidly in an emergency by personnel unskilled in transvenous pacing. However, this is a temporary measure. Patches are applied anterolaterally or anteroposteriorly, over the heart. Conscious patients can experience significant pain due to pectoral muscle contraction and may require analgesia or sedation.

Other pacing modalities such as the transoesophageal route are used rarely, except in paediatrics.

PERMANENT PACING

INDICATIONS FOR PERMANENT PACING

Guidelines for permanent pacing are published by a joint American taskforce and updated fairly regularly.[2] They recommend the following pacing indications, stratified according to the likely benefit. (Please note that the vast majority of pacing indications have only levels of evidence C (expert consensus) or B (limited non-randomised trials of small numbers of patients) as pacing predated modern randomised controlled trials.)

1. *Class I:* benefit clearly outweighs risks – treatment should be performed:
   a. in second- or third-degree atrioventricular (AV) block with:
      - *symptoms* and bradycardia
      - pauses greater than 3 seconds or rate less than 40 beats per minute whilst awake, even without symptoms

  - postoperative or post-AV node ablation
  - neuromuscular disease, with or without symptoms
  - **b.** in sinus node dysfunction with documented bradycardia *and symptoms*
  - **c.** in recurrent syncope due to spontaneous carotid sinus stimulation or carotid sinus pressure and pauses greater than 3 seconds
  - **d.** in chronotropic incompetence *with symptoms*
  - **e.** in pause-dependent ventricular tachycardia.
2. *Class IIa–IIb:* benefit outweighs risks – reasonable to perform procedure or procedure can be considered:
  - **a.** in asymptomatic complete AV block with average ventricular rate 40 beats/min in an awake patient
  - **b.** in asymptomatic Mobitz type II second-degree AV block with narrow QRS
  - **c.** in asymptomatic sinus bradycardia with heart rate <40 beats/min
  - **d.** in first-degree heart block (>300 ms) in patients with depressed left ventricular function and symptoms of left ventricular failure.
3. *Class III:* risks clearly outweigh the benefits – pacing should not be performed:
  - **a.** in asymptomatic first-degree heart block
  - **b.** in reversible AV block secondary to drug toxicity.
4. Other indications: non-bradycardia indications for pacing include pacing to improve haemodynamics. Evolving indications include the following:[2,3]
  - **a.** *Heart failure*: patients with heart failure, severe left ventricular impairment and left bundle branch block (LBBB) may benefit from restoring synchronous ventricular contraction through pacing the RV and left ventricle (LV) at the same time – known as biventricular pacing. Such cardiac resynchronisation therapy (CRT) improves symptoms of heart failure and survival in about two-thirds of these patients. Patients who benefit most are those in sinus rhythm, have QRS widths greater than 150 ms and NYHA class II–IV heart failure symptoms.[4,5] Some patients with dys-synchronous LV contraction on echocardiography but narrow QRS width can also benefit. The use of CRT via a permanently implantable biventricular pacemaker (the LV lead is usually passed via a tributary of the coronary sinus to the epicardial surface of the LV) has gained widespread acceptance for treatment of heart failure, together with appropriate medications. Temporary biventricular pacing with a temporary transvenous pacemaker lead passed to a coronary vein via the coronary sinus has been used successfully in cardiogenic shock and high-degree AV block.[6] Permanent devices combining CRT and ICDs, known as CRT-D, are used in those who fulfil CRT criteria and have an indication for an ICD.
  - **b.** *Hypertrophic cardiomyopathy (HCM)*: pacing can be used in symptomatic patients with a high gradient in the left ventricle. Right ventricular apical pacing causes dys-synchronous ventricular activation and can decrease LV gradient and systolic anterior motion (SAM) of the mitral valve. However, the evidence to support this is weak (currently a class IIb indication) and is probably helpful in only a small proportion of suitable patients.

PACEMAKER MODES

The Heart Rhythm Society (HRS), previously known as the North American Society of Pacing and Electrophysiology (NASPE), and Heart Rhythm UK, previously the British Pacing and Electrophysiology Group (BPEG), developed the NBG code[7] for pacing. This is a generic code used to identify modes of pacing (**Table 23.1**). The code was updated in 2002 to include multisite pacing therapy (position V)[8]:

- *Position I:* refers to the chamber(s) paced: A=atrium, V=ventricle, and D=dual chamber, i.e. both A and V.
- *Position II:* refers to chamber(s) in which sensing occurs: A=atrium, V=ventricle, and D=dual chamber, i.e. both A and V, O=no sensing.
- *Position III:* refers to the pacemaker's response to a sensed event. This may be:
  - I (inhibition) – a pacemaker's discharge is inhibited (switched off) by a sensed signal, for example, VVI, where ventricular pacing is inhibited by spontaneous ventricular activity.

Table 23.1 The North American and British Group (NBG) pacemaker code

POSITION I	POSITION II	POSITION III	POSITION IV	POSITION V
Chamber(s) paced	Chamber(s) sensed	Response to sensing	Rate modulation	Multisite pacing
O=none	O=none	O=none	O=none	O=none
A=atrium	A=atrium	T=triggered	R=rate modulation	A=atrium
V=ventricle	V=ventricle	I=inhibited		V=ventricle
D=dual	D=dual	D=dual		D=dual

Note: Positions I–III are used exclusively for antibradycardia function.
(Reproduced from Bernstein AD, Daubert JC, Fletcher RD, et al. Pacing. Clin Electrophysiol 2002;25:260.)

- T (triggered) – a pacemaker's discharge is triggered by a sensed signal.
- D (dual) – both T and I responses can occur. This designation is reserved for dual-chamber systems. A depolarisation sensed in the atrium inhibits the atrial output but triggers ventricular pacing. There is, however, a delay (the AV interval) between the sensed atrial depolarisation and the triggered ventricular pacing, which mimics the normal P–R interval. If a spontaneous ventricular depolarisation is sensed, ventricular pacing is inhibited.
- O – no action.

- *Position IV:* refers to *R* or rate response and is only relevant to permanent pacing systems. An *R* indicates that the pacemaker incorporates a sensor(s) to vary the pacing rate independent of intrinsic cardiac activity. The sensor(s)[9] increases or decreases the heart rate according to the body's metabolic needs. They are useful for patients with impaired sinus node function, chronotropic incompetence (when heart rate does not increase appropriately with exercise) and patients with atrial fibrillation and complete heart block or slow ventricular rates. Two different sensors are widely used:
  1. Activity sensors with vibration detectors (accelerometer or piezoelectric crystal) increase heart rate when movement is detected. They have the disadvantage that they may respond to non-physiological stimuli (e.g. pacing rate increase may occur when the patient is using an electrical drill).
  2. Minute ventilation sensors (respiratory rate times tidal volume, which is estimated by measuring impedance differences between the pacing electrode and the pacemaker unit) rely on minute volume changes to alter the pacing rate. This sensor may occasionally inappropriately accelerate the pacing rate (e.g. in a mechanically ventilated patient requiring a large minute volume). Changing the 'upper rate' limit of the pacemaker or switching the rate-adaptive function 'off' will usually solve the problem. Other sensors, such as ventricular paced Q–T interval systems, are also used in clinical practice. Recently rate-adaptive systems with dual sensors, where one sensor cross-checks the other and only responds if both sensors are receiving consistent data, have become available. All modern permanent pacemakers are programmable and the degree of rate response can be modified to optimise heart rate with exercise.
- *Position V:* is used to indicate whether multisite pacing is present
  O = none of the cardiac chambers
  A = atrium
  V = one or both ventricles
  D = any combination of atria and ventricles.

For example, the code for a patient with dual-chamber, rate-responsive pacing (DDDR) and biventricular pacing is DDDRV.

SPECIFIC PACING MODES

The three-position code (**Fig. 23.1**) is adequate to describe emergency temporary pacing and most forms of permanent pacing in the intensive care unit (ICU) (**Table 23.2**).

SINGLE-CHAMBER PACING

1. *AOO and VOO (asynchronous atrial and ventricular) pacing:* in this mode there is no ability to sense cardiac activity (**Fig. 23.2**) and it is useful during and after cardiac surgery or when a patient is exposed to external sources of noise (e.g. surgical diathermy or MRI scanning).
2. *AAI (atrial demand) pacing:* this is indicated in patients with sinus bradycardia and intact AV conduction. It is reserved for patients in whom the risk of developing AV block is thought to be low.
3. *VVI (ventricular demand) pacing (**Fig. 23.3**):* this is the most commonly used mode and the mode of choice in life-threatening bradyarrhythmias. Spontaneous cardiac rhythm is sensed and a minimum ventricular rate is programmed to prevent symptoms or in the ICU setting to also optimise cardiac output. There is a low risk of pacemaker-induced ventricular tachyarrhythmia (**Fig. 23.4**), but AV synchrony is lost, which may depress cardiac output and blood pressure.

DUAL-CHAMBER PACING

Two sets of electrodes are required (atrial and ventricular).

1. *DDD pacing:* there is pacing and sensing in both chambers (**Fig. 23.5**). An atrial impulse will trigger a ventricular output if none is seen after the programmed AV delay and will simultaneously inhibit an atrial output. If the impulse is conducted normally to the ventricle, ventricular pacing is inhibited. An upper rate limit is programmed to prevent the pacemaker tracking fast atrial rates (e.g. in atrial flutter or tachycardia). The response to DDD pacing depends on the underlying cardiac rhythm:
   a. atrial bradycardia with intact AV conduction – atrial pacing
   b. normal sinus rhythm with high-degree AV block – tracking of P-waves and ventricular pacing
   c. sinus bradycardia with AV block – sequential atrial and ventricular pacing
   d. normal sinus rhythm and AV conduction – inhibition of both atrial and ventricular pacing.

   Pacemaker-mediated tachycardia (PMT), or 'endless-loop' tachycardia,[10] can occur in

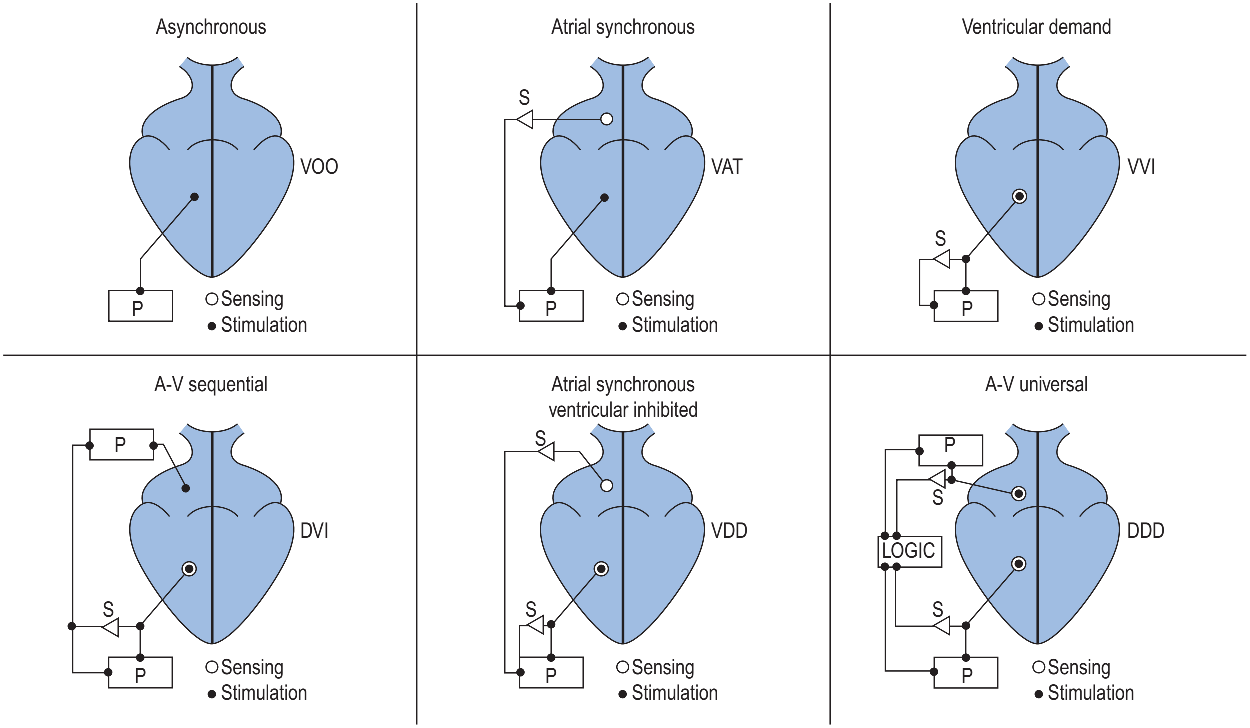

Figure 23.1 Examples of pacemaker modes and their three-position (letter) codes. P=pacemaker; S=sensing.

Table 23.2 Examples of pacemaker modes

MODE	
VOO	Paces the ventricle, no sensing, fixed-rate, asynchronous Usually only used for pacemaker testing, during use of diathermy and 'emergency' pacing
VVI	Paces the ventricle, senses ventricular activity, ventricular activity inhibits the pacemaker Ventricular demand
AAI	Paces the atrium, senses atrial activity, atrial activity inhibits the pacemaker Atrial demand Indicated in sinus bradycardia with intact AV conduction
DDD	Paces and senses both atrium and ventricle: atrial activity triggers ventricular pacing
DDI	Paces and senses both atrium and ventricle Atrial activity not tracked; thus atrial tachyarrhythmias do not trigger rapid atrial pacing AV sequential, non-P synchronous Useful for sinus bradycardia with AV block and intermittent atrial tachyarrhythmias

dual-chamber pacing systems where a ventricular premature beat (**Fig. 23.6**) conducted retrogradely to the atria is sensed and ventricular pacing is triggered resulting in an endless loop: the circuit's anterograde limb is the pacemaker, and the retrograde limb is via the AV node. This can be prevented by programming a blanking period after a ventricular-paced beat so that retrograde atrial activity is not sensed. The blanking period is known as the post-ventricular atrial refractory period, or PVARP, and is found on all modern pacemakers. An alternative is to switch to an asynchronous (non-sensing) mode or programming to DDI mode.

2. *DDI pacing (AV sequential, non-P-wave synchronous):* in this mode sensing occurs in both atrium and ventricle, but sensed atrial events do not trigger ventricular pacing. Imagine it as a patient with separate VVI and AAI pacemakers that cannot talk to each other. PMT or endless-loop tachycardia cannot occur in

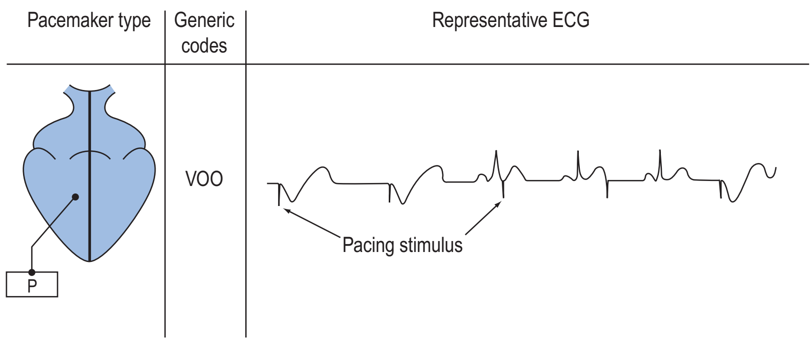

Figure 23.2 Fixed-rate ventricular pacing VOO. P=pacemaker.

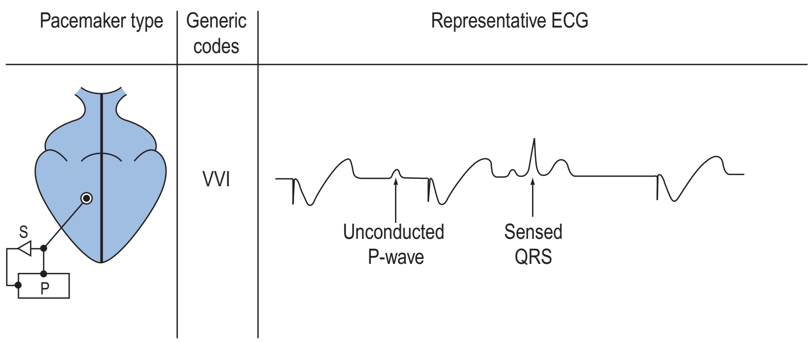

Figure 23.3 Ventricular demand pacing VVI. P=pacemaker; S=sensing.

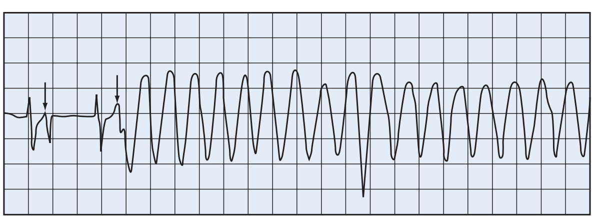

Figure 23.4 Non-sensing of QRS (see first two beats). Pacing spikes (arrows) fall on the T-wave with subsequent pacemaker-induced ventricular tachycardia.

DDI and neither will tracking of rapid atrial rates. For this reason, modern pacemakers programmed DDD will switch to DDI when an atrial tachyarrhythmia is detected (e.g. atrial fibrillation). When this happens the pacemaker will simply pace the ventricle at its back-up rate and not track the tachycardia.

HAEMODYNAMICS OF CARDIAC PACING AND THE AV INTERVAL

In the normal heart, cardiac output increases three- to fourfold during exercise, mainly due to increased heart rate and stroke volume and the ability of pacemakers to increase heart rate is therefore paramount. Nevertheless, loss of AV synchrony (i.e. the normal activation sequence of atria contracting first and then the ventricles) will decrease cardiac output by up to 25%,[11] most commonly in atrial fibrillation. Many permanent pacemakers are rate-adaptive. When temporary pacing is used, especially in the ICU setting, higher than normal lower rates may be needed if oxygen delivery is inadequate. For life-threatening bradyarrhythmias, increasing heart rate with VVI mode pacing is the treatment of choice and heart rate modulation with exercise is required only for permanent pacemaker patients.

During VVI and VVIR pacing, the atria and ventricles beat independently and AV synchrony is lost. This can have deleterious effects, known collectively as 'pacemaker syndrome'.[12] It can occur with any pacing mode where AV dissociation occurs and blood pressure, stroke volume and cardiac output may fall with the onset of pacing. Another feature is due to the atria contracting against closed tricuspid and mitral valves causing regurgitation of blood into the neck via the jugular veins. This is felt as uncomfortable neck pulsations. The pacemaker syndrome can be eliminated by restoring AV synchrony.

However, and somewhat counterintuitively, dual-chamber pacing has not been shown to improve mortality even though haemodynamics are usually superior to VVI pacing.[13] It does though appear to lower the incidence of AF.[3]

Changing the programmed AV interval of a dual-chamber pacemaker can affect the amount of ventricular pacing that is seen and also the haemodynamics, for the reasons outlined above. If this interval is programmed short (e.g. 80 ms), it will promote ventricular

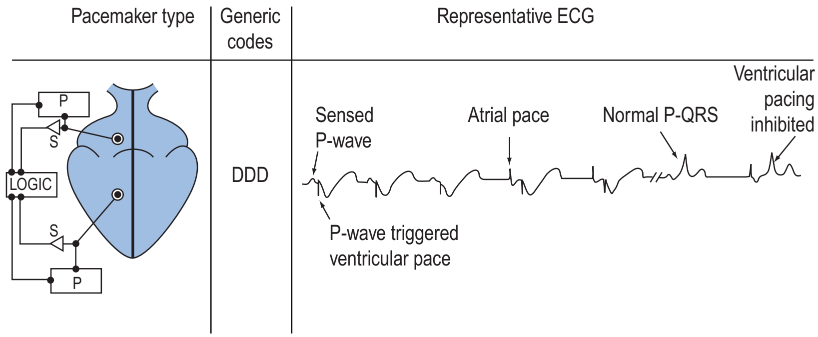

Figure 23.5 DDD pacing. P=pacing; S=sensing.

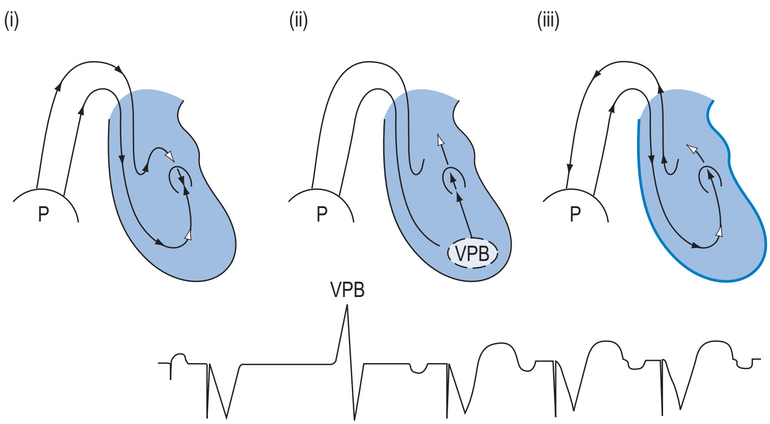

Figure 23.6 Pacemaker-mediated 'endless-loop' tachycardia: (i) under normal conditions (first beat) there is no conduction from the ventricles to the atria because of ventriculo-atrial (VA) block or because the atrial and ventricular impulses collide and extinguish each other in the atrioventricular node; (ii) if a ventricular premature beat (VPB) is conducted retrogradely to the atria (second beat), inducing an inverted 'p'-wave, this may be sensed by the pacemaker (P) which then triggers a ventricular paced beat (third beat); (iii) if the paced ventricular beat is then retrogradely conducted from the ventricle to the atria and sensed, an 'endless loop' may occur (beats 4, 5); that is, pace ventricle VA conduction 'p' wave (sensed) ventricular pace, and so forth.

pacing. If it is programmed long (e.g. 250 ms), it will promote intrinsic ventricular activity (if present). The correct AV interval will depend on patients' clinical state and their intrinsic AV conduction and inter-atrial conduction (the time to conduct between the RA and LA). Promoting ventricular pacing may be a good thing if it improves haemodynamics, but promoting intrinsic conduction is often better especially if the intrinsic AV delay is not very long. Adjusting the AV interval in the patient with poor cardiac output or low oxygen delivery can be optimised using echocardiography or thermodilution assessment of cardiac output.

TEMPORARY PACING

INDICATIONS FOR TEMPORARY PACING

Temporary cardiac pacing is indicated for:

- any sustained symptomatic bradycardia not promptly responding to medical treatment
- malignant ventricular arrhythmias secondary to bradycardia
- second- or third-degree AV block with haemodynamic compromise
- asystole.

The decision to pace is based on bradycardia causing haemodynamic deterioration, and not on the specific rhythm disturbance. For example, pacing is indicated in a patient with atrial fibrillation and a ventricular rate of 40 beats per minute associated with a blood pressure of 70/40 mmHg (9.3/5.3 kPa), cardiac failure and oliguria, but not in an asymptomatic, normotensive patient with the same rhythm or even a patient with an inferior myocardial infarction, complete heart block and a ventricular rate of 45 beats per minute with a narrow QRS complex.

Temporary pacing is indicated for the treatment of heart block or sinus bradycardia after cardiac surgery. In high-risk patients (e.g. aortic or mitral valve replacement), prophylactic epicardial electrodes are attached

during surgery. DDD epicardial pacing has been shown to increase cardiac output at any given heart rate compared with VVI pacing.[14] Temporary perioperative cardiac-pacing strategies to increase stroke volume and cardiac output include optimisation of AV delay and rarely multisite pacing.[15] Temporary pacing may be required in patients with inferior myocardial infarction or during coronary angioplasty, particularly of the right coronary, which supplies the SA and AV nodes. Asymptomatic patients with bifascicular block do not require prophylactic pacing prior to general anaesthesia, although transcutaneous pacing should be available, but should be considered for all patients with trifascicular block (bifascicular block and prolonged PR interval). Patients with Mobitz type II or third-degree AV block should be paced prior to general anaesthesia and surgery.

Caution should be exercised in patients with acute myocardial infarction as many will have received antiplatelet agents. Transcutaneous pacing prevents the need for transvenous pacing, but should only be used as an emergency in high-risk patients.

TEMPORARY LEADS AVAILABLE

VENTRICULAR PACING LEADS

There are different types of temporary pacing lead available with different degrees of rigidity and French size. The commonest calibres will be 4–6 F. These leads are relatively stiff and can be shaped before advancing through a sheath, but are still flexible enough to be manipulated under fluoroscopic control to the correct position in the RV. Balloon-flotation leads can, in theory, float into a stable position in the RV and are useful if fluoroscopy is not available in emergent situations, or as back-up when transferring patients to centres for permanent pacing. There are also active fixation temporary pacing leads, which have a fixed screw at the distal tip. This screw can be inserted into myocardium by rotating the lead body. Care should be taken with these leads as the risk of perforation is higher than for passive leads.

ATRIAL PACING LEADS

Leads designed specifically for placement in the right atrium have a preformed J-shaped tip designed to hook into the RA appendage. This site is often best for lead stability, low pacing thresholds and good sensing.

TECHNIQUE OF TEMPORARY TRANSVENOUS PACING

VENTRICULAR PACING

A sterile technique is mandatory in an environment with good fluoroscopic imaging, non-invasive cardiac monitoring and resuscitation facilities. In emergencies, transcutaneous pacing (VVI) can be implemented first while transvenous VVI pacing is being prepared. A bipolar lead introduced under fluoroscopic control is most commonly used.

Vascular access

The Seldinger technique is employed to access a central vein with a 5 or 6 French sheath. The sheath has a haemostatic valve, which prevents blood loss at the time of lead insertion. Percutaneous insertion via the right internal jugular vein probably offers least complications with ease of manipulation and stability of the lead. However, the subclavian vein approach is often used as it allows more freedom for arm and neck movement, but there is a slightly greater risk of pneumothorax. Patients likely to need permanent pacing later in their treatment should have the left subclavian vein saved for this purpose. Antecubital veins are associated with lead instability and thrombophlebitis. The femoral vein can be used. It is usually quick and easy to insert a ventricular pacing wire from this route, but the patient must remain lying flat. Lead stability is probably less good than superior routes and there is higher risk of infection and deep-vein thrombosis. Femoral temporary pacing is useful over a short period of time, for instance to cover a surgical procedure in a patient with trifascicular block or those who have received thrombolytic agents but should not be used for longer-term pacing if possible.

Positioning the pacing lead

The pacing lead is manipulated under fluoroscopic control in the posteroanterior (PA) position close to the apex of the RV (**Fig. 23.7**). This position offers the greatest stability, but the true apex should be avoided as it is thin and the risk of perforation is higher. As the lead crosses the tricuspid valve to the RV, it is usual to see ventricular ectopy (VE). However, if continuous, the lead should be pulled back to the right atrium. In the

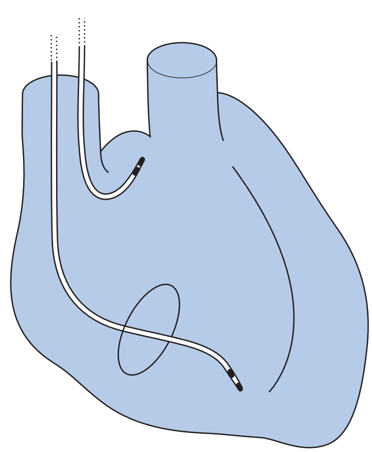

Figure 23.7 Characteristic appearance of temporary transvenous pacing leads ideally positioned in the right atrium (right atrial appendage) and apex of right ventricle.

absence of VE, the lead position should be confirmed in the left anterior oblique (LAO) position to ensure it is not in the coronary sinus or a posterior vein. Manipulation of the lead is achieved by clockwise and counterclockwise torque in combination with simultaneous advancement and retraction of the lead. Temporary pacing leads are relatively stiff and perforation can occur, especially if leads are seen to buckle whilst advancing, but it is also important to ensure sufficient slack in the lead to avoid the loss of position with subsequent patient movement.

Once in a satisfactory position, the lead should be tested electrically for sensing, pacing and diaphragmatic capture (see below). It should be sutured to the skin at two different sites: one where it exits the skin, and a second to a loop formed with the lead. A chest X-ray should be obtained to exclude pneumothorax and to confirm satisfactory positioning.

ATRIAL PACING

J-shaped atrial leads are designed to be advanced and hooked into the right atrial appendage. The appendage is an anterior structure, which is superior to the right atrium. Once the tip is advanced into the appendage orifice, retraction of the lead will hook the tip into the appendage body and a side-to-side motion of the lead tip may be seen if the patient is in sinus rhythm. The correct position is best confirmed by a lateral chest X-ray.

DUAL-CHAMBER PACING

Modern external pacing boxes are available (**Fig. 23.8**) that will pace in all modes. These units are small, easy to use and can fit into a small pouch suitable for mobile patients.

Figure 23.8 External pacemakers. Medtronic, Inc. (i) Model 5388 (dual-chamber); (ii) model 5348 (single-chamber). Both are capable of rapid pacing for certain tachycardias.

Troubleshooting

Lead does not cross the tricuspid valve Looping the lead in the right atrium and then applying counterclockwise torque will help prolapse it into the RV.

Lead cannot be advanced to the RV apex Withdrawing the lead after advancing it to the RV outflow tract (RVOT) may help the tip fall towards the apex. A small amount of torque may aid the process. Alternatively, the lead may need to be shaped with a different degree of curve.

If this manoeuvre does not help, a more basal position on the inferior wall can be used. The RVOT should be used only if the patient is asystolic as lead stability is poor here with passive leads.

Lead advances only towards the RVOT Ensure that this is not in the coronary sinus by checking that it does not curve posteriorly in the LAO position. If it is not, apply a slightly posteriorly facing curve to the distal tip of the lead and try again.

Testing the pacing leads

Modern temporary pacing boxes are sophisticated devices, which can perform checks of sensing as well as pacing threshold. Checking the sensitivity of a pacing lead electrogram is a very important step. Sensitivity, or sensing, is simply calculation of the amplitude of the sensed electrograms. Large electrograms are easy to sense and small ones are not and undersensing may occur. Undersensing will cause inappropriate delivery of a pacing stimulus. If this occurs on or near a T-wave, this can lead to ventricular fibrillation (VF). On most boxes sensing is indicated by a flashing light or other digital marker. The sensitivity dial is slowly rotated from a low value to a higher one until sensing stops. This represents the sensitivity of the sensed electrograms. A higher value is better than a lower one. The sensitivity is programmed to allow continuous sensing of all intrinsic signals.

Pacing threshold The rate should be set at least 10 beats per minute faster than the intrinsic heart rate, or at 60 beats per minute if the patient has a profound bradycardia. The pacing output should be set at 5 V and sensitivity at 1 mA. The box is switched on and ventricular capture confirmed by the presence of a pacing spike immediately followed by a broad QRS of LBBB morphology at the same rate as that set on the box.

The output is slowly decreased until consistent capture is lost. It is then increased until capture returns. This is the pacing threshold and ideally should be less than 1 V. However, if another stable position cannot be found then a higher threshold may be acceptable. In those with no underlying rhythm or profound bradycardia, loss of capture will lead to asystole – in which case the output should be rapidly increased until capture returns. The stability of the wire is checked in its position just above the pacing threshold by asking the patient to take deep breaths, cough and

sniff whilst looking for loss of capture and viewing the wire fluoroscopically. Diaphragmatic capture is checked in leads on the inferior RV wall by pacing at the maximum output, usually 10 V, and feeling the abdomen or fluoroscopically screening the diaphragm. If diaphragmatic capture occurs, the lead must be repositioned.

If a threshold of less than 1 V is achieved, the pacing rate is set to the desired rate to achieve adequate cardiac output or 40 beats per minute if intermittent back-up pacing is required. The voltage is usually set to three times the pacing threshold to allow sufficient safety margin, or at least 3 V. Temporary pacing is programmed in VVI mode to allow sensing of spontaneous ventricular activity and to inhibit pacing.

Complications of temporary pacing[16]

Temporary pacing should have a low complication rate. However, it is rare nowadays for operators to gain regular experience at insertion and similarly training may also be inadequate. Several studies from the UK report complications in a third to a half of cases.[17,18] Thus, temporary transvenous pacing is best avoided where possible; rather, insertion of a permanent system at the earliest opportunity is best, and in many centres this now happens out of 'normal' working hours. Complications include:

- pneumothorax, haemothorax, arterial puncture, AV fistula and perforation of the RV or RA leading to cardiac tamponade
- undersensing, leading to inappropriate pacing and pacemaker-induced arrhythmias; oversensing (of extrinsic or intrinsic noise), with pacemaker inhibition and loss of cardiac output; failure to capture due to poor or unstable lead position, increasing pacing threshold with chronicity of lead
- diaphragmatic capture (may be associated with RV perforation)
- thrombus of the central vein and importantly infection, especially with leads older than 7 days.

How to manage abrupt failure to pace

A life-threatening situation may arise if a temporary pacemaker fails suddenly. The following is an ordered approach to such an emergency:

1. Make sure the pacemaker box is switched on and connected to the pacing lead(s).
2. The pacemaker output should be increased to its maximum setting (usually 10 V or 20 mA).
3. Asynchronous DOO/VOO mode(s) should be selected to prevent oversensing.
4. If pacing still fails, connect the pacemaker directly to the pacing lead bypassing the connecting wire (if present), as occasionally connecting wires may be faulty.
5. Consider replacing the pacemaker box or its batteries.
6. External transcutaneous pacing should be immediately available and commenced while a new pacing system is inserted.
7. Cardiopulmonary resuscitation and positive chronotropic drugs such as atropine, isoproterenol (isoprenaline) or epinephrine (adrenaline) should be available.

PACEMAKER PROGRAMMING

Multiple parameters can be programmed on both modern temporary and permanent pacing systems. All pacing practitioners, and this includes physicians who implant temporary systems, should be familiar with programming the mode, rate, pacing output and sensitivity of a pacing system and should also be able to diagnose and troubleshoot basic pacing problems like undersensing and oversensing. If dual-chamber pacing systems are used, programming the AV delay should be performed to optimise cardiac output and cardiac function (perhaps using echocardiographic guidance). Programming permanent pacing systems is more complicated than for temporary systems and should be performed only by individuals qualified to do so. Internationally recognised pacing qualifications include the IBHRE and EHRA examinations awarded by the Heart Rhythm Society and the European Heart Rhythm Association, respectively.

NOISE AND ELECTROMAGNETIC INTERFERENCE

Any signal sensed by a pacemaker will lead to pacing being inhibited or triggered (e.g. in dual-chamber systems). These signals will include noise, or electrical artefact sensed by a pacing system. Noise is characterised as intrinsic (from within the patient) or extrinsic, from outside the patient. Sources of intrinsic noise include lead fracture, fluid in the generator header and diaphragmatic and skeletal myopotentials. Extrinsic noise includes electromagnetic interference (EMI) (e.g. from a nearby electrical device or its trailing wires and surgical diathermy). Other sources include MRI scanners (patients with some modern permanent pacemakers can be safely scanned in MRI scanners) or electronic devices placed over the pacemaker generator (e.g. mobile telephones or MP3 players). Noise can be misinterpreted by ICDs as VT or VF and can result in inappropriate therapy and shocks.

MRI scanning is sometimes necessary in patients with non-MRI-safe pacing systems or ICDs. Recent studies have demonstrated that MRI scanning can be performed safely in selected patients with these types of system,[19] but this must be performed in collaboration with a pacing expert and the risks presented by MRI must be outweighed by the diagnostic benefit of the scan on a case-by-case basis.

CARDIOVERSION/DEFIBRILLATION IN PATIENTS WITH A PERMANENT PACEMAKER (OR ICD)

To avoid damage to the pacemaker device, shocking pads should be placed in the anterior–posterior position and at least 10 cm from the unit. The pacemaker (or ICD) should be checked before and afterwards. In patients with a temporary transvenous pacemaker, the external unit and leads should be kept well away from the pads.

DIATHERMY

Bipolar diathermy should be used whenever possible and the pacemaker programmed to an asynchronous mode in pacing-dependent patients. In an emergency (e.g. asystole in a patient whose pacemaker is inhibited by diathermy), placing a magnet over the pacemaker generator will result in asynchronous pacing at 'magnet' rate (magnet rate varies according to pacemaker manufacturer). ICDs do not have a magnet rate; placing a magnet over an ICD will switch off its therapies (i.e. antitachycardia pacing and shocks) but ICD therapies should be switched off before using diathermy. After surgery the pacemaker or ICD should be tested and reprogrammed appropriately.

CARDIAC PACING IN TACHYARRHYTHMIAS

Although pacemakers are not usually inserted for the treatment of atrial arrhythmias, AVNRT or AVRT, these rhythms may be treated safely and effectively by rapid pacing and/or premature electrical stimulation where a device is already present. They can also be used for treatment of VT, but rapid VT should be managed with DC cardioversion. Rapid cardiac pacing has advantages over DC cardioversion (**Box 23.1**) and drug therapy (**Box 23.2**), but is of no value in sinus tachycardia, AF and VF (**Box 23.3**). Pacing at rates of 80–100 beats per minute can be used to try to suppress ventricular and supraventricular rhythms as well as torsade de pointes in patients with the congenital long QT syndrome.

VENTRICULAR TACHYCARDIA

Ventricular burst pacing is a simple and often effective technique to pace VT. The ventricle is paced at a rate starting at about 120% of the VT rate for 8–10 beats (Fig. 23.9). If this fails (Fig. 23.10), increasing the pacing rate and/or the number of paced beats in the train should be tried cautiously. Slow VTs particularly are very stable and often require very long pacing trains. Potential complications include accelerating the VT rate, which can precipitate VF. Trained personnel, a defibrillator and resuscitation facilities must be available to perform this safely.

Box 23.1 Pacing versus cardioversion for the treatment of tachyarrhythmias

- Pacing may assist in rhythm diagnosis
- Pacing may be used (cautiously) in digitalis intoxication
- Pacing does not require a general anaesthetic
- Pacing avoids complications of DC shock, especially myocardial depression
- Repeated reversions are easier with pacing
- Standby pacing is immediately available if bradycardia or asystole occurs after electrical reversion

Box 23.2 Pacing versus drug therapy for the treatment of tachyarrhythmias

- Pacing may aid in arrhythmia diagnosis
- Pacing avoids drug-induced cardiac depression and other drug side-effects
- Pacing can be used when drug therapy has failed
- Termination of the tachycardia with pacing is often immediate
- Standby pacing is immediately available

Box 23.3 Indications for rapid cardiac pacing in suitable arrhythmias

- Failure of drug therapy
- Recurrent arrhythmias
- Contraindication for cardioversion (e.g. digitalis intoxication)
- Aid to arrhythmia diagnosis (e.g. wide-complex tachycardia to differentiate ventricular tachycardia from supraventricular tachycardia)

Figure 23.9 Wide-complex tachycardia. Ventricular burst pacing with ventricular capture results in normal sinus rhythm on cessation of pacing.

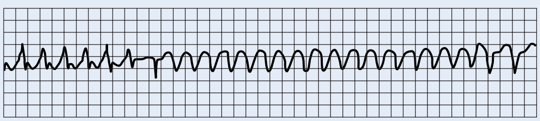

Figure 23.10 Wide-complex tachycardia is followed by ventricular burst pacing. When pacing is discontinued, a wide-complex tachycardia of opposite polarity is precipitated.

IMPLANTABLE CARDIOVERTER DEFIBRILLATORS (ICD)

This is an implantable device that recognises and tries to terminate VT and VF through antitachycardia pacing and shocks, respectively. Guidelines are published for ICD implantation.[14] ICDs are of proven survival benefit and a class I indication in patients who have survived VF or haemodynamically unstable VT not due to a transient or reversible cause (e.g. an electrolyte imbalance). ICD implantation is also indicated for patients with structural heart disease and spontaneous sustained VT, whether haemodynamically stable or unstable. ICDs are also now used prophylactically in high-risk patients (i.e. those with severely impaired LV function) and are especially efficacious in patients with previous myocardial infarction.[20]

Most ICD systems are implanted transvenously and can perform antitachycardia pacing as well as normal permanent pacing, if necessary. Single- or dual-chamber ICDs may be implanted. The addition of an atrial lead gives another piece of information for the ICD to use to diagnose a tachycardia as VT rather than an SVT, but has not conclusively been shown to do this better than single-chamber devices. ICDs continuously monitor the patient's heart rate and deliver therapy when the heart rate exceeds the programmed detection rate. Devices are programmed with different tachycardia zones, stratified according to rate:

1. *VF zone:* for rates usually faster than 200 beats per minute. High-energy shocks are delivered if detection criteria are met, but antitachycardia pacing can be delivered while the device is charging in case it is a very fast VT. Shocks are biphasic as these are more efficient and require lower energies than monophasic waveforms and can be programmed below the maximum output if the programmer wishes to save device battery life.
2. *Fast VT zone:* for rates between 170 and 200 beats per minute – several attempts of antitachycardia pacing are usually programmed initially, of increasing aggressiveness. This is followed by shocks if unsuccessful.
3. *Slow VT zone:* for rates between 150 and 170 beats per minute. This is similar to the fast VT zone, but even more weighted to antitachycardia pacing.

COMPLICATIONS

Occasionally, ICDs can deliver multiple discharges in short sequence and this is a clinical emergency. Shocks may be appropriate or inappropriate. Frequent malignant ventricular arrhythmias may result in multiple appropriate discharges. If the multiple shocks are successful in defibrillating the patient during an arrhythmia 'storm', the ICD device may be deactivated and antiarrhythmic drugs or even general anaesthesia initiated. This will save device battery longevity and be much more comfortable for the patient. If shocks are inappropriate, for example for atrial fibrillation or lead fracture, the ICD needs to be reprogrammed or should be switched off.

Acute heart failure

Nicholas Ioannou, Pratik Sinha and David Treacher

The pattern of heart failure seen in the community, outpatients clinics and specialist cardiac wards is dominated by the acute coronary syndromes and chronic heart failure, predominantly caused by ischaemic heart disease and hypertension.[1,2] Heart failure is the commonest cause of hospital admission in people over 65 years of age and it has been estimated that in North America and Europe over 15 million patients have heart failure and 1.5 million new cases are diagnosed each year.[3] Patients present with chest pain, palpitations, shortness of breath, fatigue and oedema and will usually have single-organ failure. Management focuses on reducing cardiac work to relieve symptoms and prevent further myocardial damage.

Patients either admitted with or who develop acute heart failure on the intensive care unit (ICU) frequently have overt or occult underlying coronary artery disease, but will usually have significant other organ dysfunction. Management in this setting focuses on both improving global and regional oxygen delivery and maintaining perfusion pressure, often with the use of drugs that stimulate rather than rest the myocardium.[4,5] The resolution of this apparent paradox requires that for each patient management should attempt to achieve the frequently difficult balance between the best interests of the myocardium and the circulatory requirements of the other vital organs. The critical care physician should target the minimum necessary oxygen delivery and arterial pressure to maintain other organ function at maximum cardiac efficiency (e.g. ensuring adequate fluid resuscitation before starting beta agonists) so that cardiac work and the risk of myocardial ischaemia and necrosis from exuberant beta agonist use are minimised and the cardiologist should consider the wider circulation and other organ requirements when instituting strategies to protect the myocardium.

DIAGNOSIS OF ACUTE HEART FAILURE

The diagnosis of acute heart failure in critically ill patients can be more difficult than is commonly recognised. Although the underlying pathology in most patients with acute heart failure on intensive care will be coronary artery disease, other diagnoses must be considered (**Box 24.1**).

It is also important to reassess critically the patient referred with a diagnosis of acute heart failure to decide whether this is indeed the primary problem. The history, examination and initial investigations with routine blood tests, electrocardiogram (ECG) and chest X-ray may be compatible with this diagnosis but many such patients are elderly with multiple co-morbidities, and deciding whether the patient is suffering from a primary myocardial pathology as opposed to a pulmonary problem or indeed systemic sepsis[6] can be difficult. Equally, patients believed to have a primary respiratory problem may fail to wean from ventilatory support because of a failure to realise that they have left ventricular failure with a high left atrial pressure and incipient pulmonary oedema, causing a reduction in pulmonary compliance, an increased work of breathing and respiratory distress when ventilatory support is withdrawn.

Further investigations that can help to confirm or refute an initial diagnosis of acute heart failure are echocardiography and the measurement of biomarkers such as natriuretic peptides and cardiac troponins.

ECHOCARDIOGRAPHY (SEE CH. 27)

Echocardiography is an extremely valuable investigation in the management of the critically ill patient with acute heart failure[7] and the modern critical care physician should at least be able to perform a basic examination. Transthoracic echocardiography (TTE) is non-invasive and can be performed rapidly at the bedside. The images obtained with TTE may be suboptimal in ventilated patients but experienced operators can achieve considerable improvement using microbubble contrast techniques.[8] If transthoracic views are difficult to obtain or if better resolution is required (e.g. for the detection of small vegetations) then transoesophageal echocardiography (TOE) should be considered. TOE gives excellent views of the aorta (dissection flaps), the left atrial appendage and left heart valves; however, right heart structures and the apex of the left ventricle are less well imaged.

Echocardiography will frequently establish the underlying cardiac pathology and can be used to monitor the response to treatment. It will:

1. Identify pericardial effusions and determine whether ventricular filling is impaired (tamponade) and whether drainage is indicated. However, ultimately tamponade is a clinical diagnosis based on the full haemodynamic picture in the context of pericardial fluid demonstrated on the echocardiogram. Many of the diagnostic features related to alterations with respiration are affected by positive-pressure ventilation and drainage may be appropriate even if such classic echocardiographic criteria are not present. Even small effusions may cause tamponade since it is the rate of accumulation of fluid rather than the amount of fluid that determines the degree of cardiac compromise.
2. Identify obstruction to cardiac filling from other intrathoracic space-occupying lesions that increase intrathoracic pressure, particularly in ventilated patients (pleural effusion, alveolar gas trapping in asthma).
3. Assess adequacy of *volume* preload of left ventricle, particularly in the context of raised preload *pressures* and monitor response to fluid challenge.
4. Identify primary valvular heart disease (critical aortic stenosis, acute mitral regurgitation from papillary muscle rupture, acute endocarditis) when urgent surgery is indicated and distinguish this from functional valvular regurgitation due to primary ventricular disease for which surgery could be lethal.
5. Identify septal defects, regional wall motion abnormalities and aneurysmal dilatation from recent or previous myocardial infarction.
6. Identify the presence of intracardiac thrombus or clot.
7. Identify increased end-systolic and diastolic dimensions, indicating ventricular contractile failure; termed systolic dysfunction or heart failure with reduced ejection fraction (HF-REF).[9] However, the use of ejection fraction as an index of ventricular dysfunction can be misleading, especially in patients on inotropic drugs.
8. Identify diastolic dysfunction as a consequence of impaired ventricular relaxation, also termed heart failure with preserved ejection fraction (HF-PEF).[9] Preserved ejection fraction in this context does not necessarily equate to an adequate cardiac output[10] and high-pressure preload measurements may fail to reflect the true volume preload and the potential need for extra fluid volume.
9. Identify pulmonary hypertension associated with tricuspid regurgitation when an estimate of pulmonary artery (PA) systolic pressure can be made.
10. Identify right ventricular size and function and discriminate between pressure and volume overload of the right ventricle. The presence of right ventricular dysfunction can also be used to diagnose and risk stratify patients presenting with suspected acute pulmonary embolism (PE).

Box 24.1 Causes of acute heart failure on the intensive care unit

Coronary artery disease
Cardiac arrhythmias – atrial fibrillation
Infection – systemic sepsis, viral myocarditis
Mechanical – endocarditis, pulmonary emboli, valve problems, septal defects, tamponade, high intrathoracic pressure with inadequate preload
Drugs – beta blockers, calcium antagonists, cytotoxic therapy (e.g. doxorubicin), alcohol, cocaine
Hypoxaemia
Metabolic – acidaemia, thiamine deficiency, thyrotoxicosis, hypocalcaemia, hypophosphataemia
Myocardial contusion – blunt thoracic trauma
Myocardial infiltration – tumour, sarcoidosis, amyloidosis
Vasculitis – rare
Neuromuscular conditions – Duchenne muscular dystrophy, Friedrich's ataxia, myotonic dystrophy

MEASUREMENT OF NATRIURETIC PEPTIDES AND CARDIAC TROPONINS

Myocardial injury and the development of acute heart failure are common but frequently unrecognised complications of critical illness occurring not only in patients with an overt acute coronary syndrome but also in other conditions such as sepsis and major pulmonary embolism.[11] Relying on blood tests alone to establish a diagnosis or to plan management is inadvisable but, when interpreted in conjunction with the wider clinical picture, natriuretic peptides and cardiac troponins appear to be sensitive markers of myocardial stress and necrosis and to have significant prognostic significance.

NATRIURETIC PEPTIDES

B-type natriuretic peptide (BNP) and *N*-terminal pro B-type natriuretic peptide (NT-proBNP) are the most commonly measured natriuretic peptides in clinical practice. BNP was first isolated from porcine brain[12] and was originally termed brain natriuretic peptide; however, the major source was subsequently shown to be from the ventricular myocardium. The main stimulus for natriuretic peptide synthesis and release is myocardial wall stress; cardiac myocytes release the prohormone proBNP, which is subsequently cleaved into biologically active BNP and the inactive *N*-terminal fragment (NT-proBNP). Although natriuretic peptide release appears to be related to end-diastolic volume and pressure, it does not reliably differentiate between HF-REF and HF-PEF or accurately predict ejection fraction or filling pressures.[13] Measurement of BNP and NT-proBNP in the emergency department may

discriminate patients with heart failure from those with pulmonary or other non-cardiac causes for acute dyspnoea and has been shown to reduce rates of ICU admission, length of hospital stay and cost.[14] Studies have demonstrated that, at a cut-off of 100 pg/mL, BNP has a sensitivity of 90% and a specificity greater than 70% as a test for excluding heart failure.[15] Similar data have also been reported for NT-proBNP.[16] Measurement of natriuretic peptides is now recommended by international guidelines for the management of heart failure.[9,17,18] Furthermore, BNP has also been shown to be a marker of myocardial dysfunction and prognosis in severe sepsis.[19]

CARDIAC TROPONINS

Troponins are regulatory proteins that form part of the thin filament of the myocyte contractile apparatus (in addition to actin and tropomyosin); three subunits have been identified: (i) TnI, which binds actin to inhibit actin–myosin interaction, (ii) TnT, which binds tropomyosin, and (iii) TnC, which binds calcium ions resulting in a conformational change in the troponin–tropomyosin complex thus exposing myosin-binding sites. The cardiac isoforms, cTnI and cTnT, are specific to the heart and can be measured in the blood after myocyte necrosis with 50% release by 4 hours, peaking at 12–24 hours and remaining elevated for up to 10 days. They are far more sensitive than traditional cardiac enzyme tests such as creatine kinase and have substantially changed the definition, diagnosis and management of acute myocardial infarction. Cardiac troponins may be released in conditions other than acute coronary ischaemia[20] such as sepsis and after chemotherapy and in the absence of evidence of myocardial necrosis, as in acute heart failure or major PE, where it is believed that the acute ventricular dilatation causes increased membrane permeability. Raised troponin levels are also associated with increased morbidity and mortality in surgical ICU patients[21] and in patients presenting with acute decompensated heart failure.[22]

Elevated levels of cardiac troponins, BNP and NT-proBNP, may also be detected in the presence of right ventricular dysfunction following an acute PE. They can be used to risk stratify patients owing to their high negative predictive value for in-hospital death and adverse events. In haemodynamically stable patients, normal values indicate a lower risk of adverse outcome; therefore less aggressive therapy may be warranted.[23–25]

Raised levels of these markers, indicating early myocardial stress, may have an important role in alerting the clinician to impending myocardial failure and the need to review the use of drugs that stimulate the myocardium and to consider the introduction of a beta blocker, particularly in the context of tachycardia.

It should be remembered that, for critically ill patients with acute heart failure not resulting from primary myocardial infarction, if the precipitating cause is successfully treated without significant myocardial necrosis occurring the acute heart failure will resolve, cardiac function will return to its premorbid state and the prognosis will be improved.

The remainder of this chapter addresses the assessment and principles of management of ventricular function in patients admitted to the ICU with acute heart failure. This inevitably involves reference to circulatory failure and the state of the peripheral circulation, but the more detailed aspects of oxygen delivery and control of the regional and microcirculation are considered elsewhere[26] (see Chs 15 and 16), as are the acute coronary syndromes[2] (see Ch. 20) and chronic heart failure.[1]

CIRCULATORY FAILURE OR 'SHOCK'

The principal function of the heart is the generation of the energy necessary to perfuse the lungs with venous blood and to propel the oxygenated arterial blood through the systemic circulation at a rate and pressure that ensure that the fluctuating metabolic requirements of the various organs are met at rest and during exercise. This should be performed at maximum efficiency so that the work performed is not at the cost of unnecessarily high myocardial energy expenditure and the risk of myocardial ischaemia is minimised.

Failure to maintain an adequate oxygen supply to the tissues with the consequent development of anaerobic cellular metabolism defines circulatory failure or 'shock', a term that benefits from brevity but little else since it implies neither cause nor prognosis, but its use is now widespread and inescapable. **Box 24.2** classifies circulatory 'shock'.

In considering these causes of circulatory failure, several points require emphasis:

1. Acute heart failure resulting in cardiogenic shock is not a pathological diagnosis but a collective term

Box 24.2 Major categories of circulatory failure or 'shock'

Cardiogenic – myocardial infarction, myocarditis, vasculitis, valve dysfunction (e.g. critical aortic stenosis, mitral regurgitation, acute endocarditis), post cardiac bypass surgery, drug overdose (beta blockers, calcium antagonists)
Hypovolaemic – haemorrhage, burns, gastrointestinal fluid loss
Obstructive – pulmonary embolus, cardiac tamponade, tension pneumothorax
Anaphylactic – drugs, blood transfusion, insect sting
Septic – bacterial infection, non-infective inflammatory conditions (e.g. pancreatitis, burns, trauma)
Neurogenic – intracranial haemorrhage, brainstem compression, spinal cord injury

that embraces all causes of myocardial failure. Treatment must focus on the underlying diagnosis.

2. Patients admitted to ICU may have acute heart failure either as the primary reason for admission (e.g. severe myocardial infarction), or develop it as part of multiple-organ failure triggered by an extracardiac cause, frequently the delayed or ineffective treatment of severe sepsis.
3. Pre-existing cardiac disease, usually ischaemic heart disease, is an important factor in determining the physiological response to critical illness. Several studies investigating the effect of manipulating oxygen delivery have demonstrated the poor prognosis associated with the inability of the heart to achieve a hyperdynamic response to critical illness either spontaneously or with volume loading and inotropic support.[4,5] Preoperative assessment with cardiopulmonary exercise testing is probably appropriate for all patients undergoing major surgery as a means of identifying those with poor physiological reserve so that the true risk of surgery can be identified and perioperative management planned accordingly.
4. Although hypotension is often considered to be the cardinal sign of circulatory failure, other global features (persistent tachycardia, confusion, tachypnoea, impaired peripheral perfusion, progressive metabolic acidaemia) occur earlier since the body has powerful homeostatic mechanisms that maintain pressure at the expense of flow.
5. The heart must provide its own blood supply and, if coronary blood flow does not match myocardial oxygen requirements, coronary ischaemia develops and cardiac and global circulatory failure may ensue.[27]
6. The primary problem in hypovolaemic, cardiogenic and obstructive shock is a progressive decline in cardiac output (CO) and global oxygen delivery, which, if not corrected, leads to secondary failure of the peripheral circulation and progressive organ dysfunction. In septic, anaphylactic and neurogenic shock, however, the primary problem is the loss of control of the peripheral circulation resulting in systemic hypotension and disordered distribution of blood flow, although CO and global oxygen delivery are usually increased.[28]
7. Although a primary cause for the circulatory failure may be identified, other causes may contribute to the evolution of the final pathology. For example, in septic shock the initial and major derangement is peripheral; it is characterised by microcirculatory chaos triggered by cytokine release, white-cell activation, disruption of the coagulation cascade resulting in microthrombi that occlude the microvasculature and endothelial disruption resulting in interstitial oedema. This same process occurs in the coronary microvasculature impairing myocyte function. There is also widespread loss of fluid from the intravascular to the extravascular space, resulting in hypovolaemia. The primary peripheral circulatory failure may therefore be compounded by both cardiogenic and hypovolaemic shock.
8. 'Early' and 'late' shock are terms that reflect the association between the duration and severity of the circulatory derangement and prognosis. Early intervention in circulatory shock has a major impact on survival.[29] If treatment is delayed until organ failure is established, the underlying pathological processes are frequently irreversible.
9. Although not a true 'mixed' venous sample, the oxygen saturation of blood taken from an internal jugular ($S_{cv}O_2$) or subclavian cannula has been shown to be valuable in assessing whether global oxygen delivery (DO_2) is adequate for global tissue oxygen consumption. A value < 70% should prompt consideration of whether a fluid challenge or other strategy to increase DO_2 is indicated. A value > 70% is not necessarily reassuring in patients with established hyperdynamic shock as this may reflect an inability of the tissues to extract and utilise oxygen.

ASSESSMENT OF VENTRICULAR FUNCTION

Making the considerable assumption that the circulation can be analysed as a constant-flow, fixed-compliance system, six key measurements traditionally define ventricular performance:

- right and left atrial pressures (RAP, LAP) or ventricular preload
- mean systemic and pulmonary arterial pressures (MAP, PAP) or ventricular afterload
- heart rate (HR)
- CO (Q_t).

Table 24.1 illustrates typical values in normal subjects and in the common causes of circulatory failure with calculation of the associated vascular resistances and oxygen delivery. The values quoted are merely examples that indicate the pattern of circulatory derangement produced by these pathologies: pre-existing cardiopulmonary disease and the severity of the condition will affect the precise figures obtained in individual cases and the response to vasoactive therapy.

Stroke volume (SV) is calculated from CO and heart rate:

$$SV = Q_t / HR \qquad (24.1)$$

Three factors determine stroke volume: (1) preload, (2) afterload, and (3) myocardial contractility.

VENTRICULAR PRELOAD

Ventricular preload, traditionally assessed from atrial filling pressures, determines the end-diastolic ventricular volume, which, according to Starling's law of the heart and depending on ventricular contractility,

Table 24.1 Measurements in a normal 75 kg adult and in various conditions causing circulatory 'shock'

	RAP (mmHg)	LAP (mmHg)	mPAP (mmHg)	MAP (mmHg)	HR (per min)	CARDIAC OUTPUT (L/min)	SVR*	PVR*	STROKE WORK (g.m)		VENOUS COMPLIANCE (mL/mmHg)	CaO_2 (mL/100mL)	DO_2 (mL/min)
									LV	*RV*

Typical circulatory measurements in a normal adult and in various cardiorespiratory conditions that may cause shock. The severity of the condition and pre-existing cardiorespiratory disease will affect the precise figures obtained in individual cases.
Pressures referenced to zero at 5th intercostal space, mid-axillary line in supine patient. LV=left ventricle; RV=right ventricle; CaO_2=arterial oxygen content; DO_2=global oxygen delivery; mPAP/MAP=mean pulmonary artery/arterial pressure.
SVR*/PVR*=systemic/pulmonary vascular resistance×80 to give SI units: dyn·s·cm^{-5}.

dictates the stroke work generated by each ventricle at the next cardiac contraction. The resulting stroke volume depends on the resistance or afterload that confronts the ventricle.[30]

On the general ward the jugular venous pressure (JVP) is measured from the sternal angle; however, in the ICU vascular pressures are measured from the mid-axillary line in the fifth intercostal space. From this reference point, in the supine position, the normal RAP is between 4 and 8 mmHg and the LAP is between 8 and 12 mmHg. Relative changes in either the contractility of the two ventricles or the respective vascular resistances will change the relationship between the atrial pressures, which must then be independently assessed.

The predominant factor determining preload is venous return, which depends on the intravascular volume and venous tone, which is controlled by the autonomic nervous system, circulating catecholamine levels and local factors, particularly PO_2, PCO_2 and pH.

The systemic venous bed is the major intravascular capacitance or reservoir of the circulation with a compliance that can vary from 30 to over 300 mL/mmHg and which provides a buffer against the effects of intravascular volume loss. It also explains the response observed in major haemorrhage and subsequent transfusion. As volume is lost, venous tone increases, preventing the large falls in atrial filling pressures and CO that would otherwise occur. If the equivalent volume is returned over the subsequent few hours the RAP gradually returns to normal as the intravascular volume is restored and the reflex increase in sympathetic tone abates. However, rapid re-infusion of the same volume does not allow sufficient time for the venous and arteriolar tone to fall and may result in the LAP rising to a level that precipitates pulmonary oedema, although the intravascular volume has only been returned to the pre-haemorrhage level and left ventricular function is normal (**Fig. 24.1**).

If the preload is low and either blood pressure or CO is inadequate, the priority is volume loading to restore intravascular volume and venous return.

Raised preload pressures reflect: (1) high intravascular volume, (2) impaired myocardial contractility, or (3) increased afterload.

Preload may be reduced by:

- removing volume from the circulation (diuretics, venesection, haemofiltration) or increasing the capacity of the vascular bed with venodilator therapy (e.g. glyceryl trinitrate, morphine[31])
- improving contractility
- reducing afterload.[32]

In assessing preload, end-diastolic *volume* rather than pressure is relevant and when interpreting atrial *pressures* as measures of preload, two points must be considered:

1. Intravascular pressure (*P*v) measurements are misleading if the intrathoracic pressure (*P*t) is raised since the true distending pressure that determines ventricular end-diastolic volume is the transmural pressure (*P*v–*P*t). This is particularly relevant if there is significant alveolar gas trapping generating intrinsic positive end-expiratory pressure (PEEP), as seen in asthma; in positive-pressure ventilation with high PEEP levels; and when an inverse inspiratory-to-expiratory time ratio is used.[33,34]
2. When the ventricle is poorly compliant, as in diastolic dysfunction, the end-diastolic pressure–volume relationship ceases to exhibit the approximately linear relationship over the normal physiological range of ventricular filling volumes (**Fig. 24.2**). Under these conditions, *pressure* will not necessarily reflect the adequacy of *volume* preload.

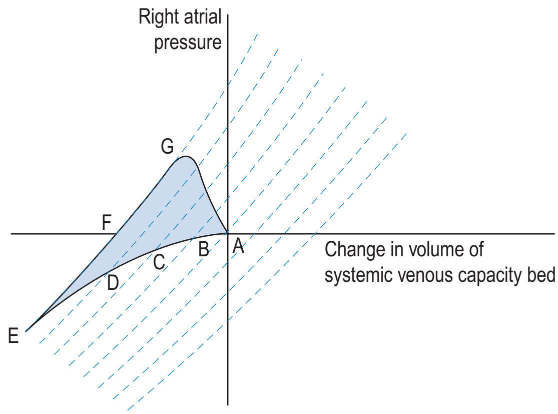

Figure 24.1 Venous compliance curves: each dotted line represents a line of constant venous compliance ranging from low compliance (increased tone) on the left to increased compliance (reduced tone) on the right. Line ABCDE shows the effect of progressive haemorrhage with the reduction in venous compliance limiting the fall in atrial pressure. Line EFGA shows the effect of rapid reinfusion of the same volume that was removed, but at a rate that does not allow the sympathetically mediated increase in venous tone to abate. Each dotted line represents a line of constant venous compliance ranging from minimum on the left to diminished venous tone on the right.

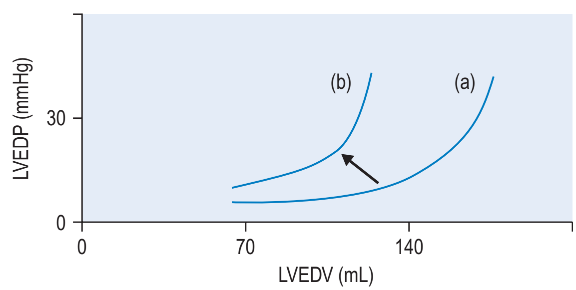

Figure 24.2 End-diastolic pressure–volume relationship (EDPVR) curves: (a) normal heart; (b) diastolic dysfunction. In the context of reduced ventricular compliance the EDPVR curve shifts upward and to the left. *(Modified from Brandis K. The Physiology Viva.[35])*

Box 24.3 Calculation of ventricular afterload and stroke work

$$\text{Systemic vascular resistance (SVR)} = [(\text{MAP} - \text{RAP})/\text{Qt}] \times 80 \text{ dyn.s.cm}^{-5}$$
$$= [(90-5)/5] \times 80 = 1360 \text{ dyn.s.cm}^{-5}$$
$$\text{SVRI} = \text{SVR} \times \text{BSA} = 1360 \times 1.65 = 2244 \text{ dyn.s.cm}^{-5}.\text{m}^{-2}$$
$$\text{Pulmonary vascular resistance (PVR)} = [(\text{mPAP} - \text{LAP})/Q_t] \times 80 \text{ dyn.s.cm}^{-5}$$
$$= [(15-10)/5] \times 80 = 80 \text{ dyn.s.cm}^{-5}$$
$$\text{PVRI} = \text{PVR} \times \text{BSA} = 80 \times 1.65 = 132 \text{ dyn.s.cm}^{-5}.\text{m}^{-2}$$
$$\text{Stroke volume (SV)} = \text{Qt/HR} = 72 \text{ mL}$$
$$\text{Stroke volume index (SVI)} = 72/1.65 = 44 \text{ mL/m}^2$$
$$\text{Ventricular stroke work (VSW)} = \text{SV} \times (\text{afterload} - \text{preload})$$
$$\text{LVSW} = \text{SV} \times (\text{MAP} - \text{LAP}) \times 0.0136 \text{ g.m}$$
$$= 72 \times (90-10) \times 0.0136 = 78 \text{ g.m}$$
$$\text{LVSWI} = 78/1.65 = 47 \text{ g.m/m}^2$$
$$\text{RVSW} = \text{SV} \times (\text{mPAP} - \text{RAP}) \times 0.0136 \text{ g.m}$$
$$= 72 \times (15-5) \times 0.0136 = 10 \text{ g.m}$$
$$\text{RVSWI} = 10/1.65 = 6 \text{ g.m/m}^2$$

MAP=mean arterial pressure; mPAP,=mean pulmonary artery pressure. Pressures are measured in mmHg, cardiac output (Q_t) in L/min. Values for resistance and stroke work are frequently indexed using the patient's body surface area (BSA) derived from height and weight. In calculating ventricular stroke work, 0.0136 converts to SI units of g.m. Example calculations assume a normal 75 kg individual with BSA 1.65 m^2.

Alternative methods of assessing ventricular preload are discussed later in this chapter under 'Assessment of intravascular volume status' and in Chapter 16.

VENTRICULAR AFTERLOAD

The vascular resistance against which each ventricle works is calculated, by analogy with Ohm's law, as the pressure gradient across the vascular bed divided by the CO (**Box 24.3**).

Circulatory management requires a clear understanding of this relationship between pressure, flow and resistance. If ventricular work is constant, increased vascular resistances produce higher pressures but with a lower CO. A systemic dilator such as sodium nitroprusside will reduce systemic resistance and blood pressure and increase CO. Although such manipulation is attractive in increasing CO for the same cardiac work, it is important to maintain a blood pressure that ensures appropriate distribution of blood flow and a diastolic pressure sufficient to maintain coronary artery perfusion, particularly in patients with known ischaemic heart disease or pre-existing hypertension.

The effects of some of the commonly used vasoactive agents are shown in **Table 24.2** and considered in more detail later (see Chs 90 and 91).

VENTRICULAR CONTRACTILITY AND EFFICIENCY

The work that the ventricle performs under given loading conditions defines contractility. For each ventricle it may be expressed mathematically as the gradient and intercept of the relationship between atrial filling pressure and stroke work (**Fig. 24.3**). The resulting stroke volume varies with the resistance of the vascular bed into which the ventricle is ejecting. Although the right ventricle generates a much smaller stroke work, the afterload (pulmonary vascular resistance) against which it ejects is correspondingly lower as the right and left ventricular stroke volumes must necessarily be the same over time.

The work generated by each ventricle with each heart beat is the ventricular stroke work and is calculated as shown in **Box 24.3**.

Consideration of ventricular work is important since optimum circulatory management requires that the necessary pressures and flows to maintain satisfactory organ perfusion and oxygen delivery are achieved at maximum cardiac efficiency (i.e. for the minimum ventricular work to avoid myocardial ischaemia). Furthermore, left ventricular efficiency is the ratio of work output to energy input and may be less than 20% in patients with acute heart failure, with over 80% of energy lost as heat.

If circulatory failure is due to impaired myocardial contractility, as defined by a 'flattened' stroke work/filling pressure equation (see **Fig. 24.3**), the atrial pressures will often already be raised. Provided such pressures reflect volume preload, further increases are not helpful since the ventricle becomes increasingly distended with high wall tension, as predicted by Laplace's law:

$$\text{wall tension} = (\text{intraventricular pressure} \times \text{radius}) \div (\text{wall thickness} \times 2) \tag{24.2}$$

This increase in wall tension compromises myocardial blood supply, particularly epicardial to endocardial blood flow, resulting in endocardial ischaemia, further impairment of ventricular contractility and the risk of pulmonary oedema developing.

The remaining therapeutic options are:

- *Reduce afterload* using an arteriolar dilator (nitrates, alpha blocker, phosphodiesterase inhibitor,

Table 24.2 Circulatory effects of commonly used vasoactive drug infusions

+=increase; 0=no change; −=decrease. These effects are guidelines only. The response will depend on the circulatory state of the patient when the drug is started.

angiotensin-converting enzyme (ACE) inhibitor), although this strategy is frequently limited by the resulting fall in systemic pressure.[36]

- *Increase myocardial contractility*, either by removing negatively inotropic influences (acidaemia, hyperkalaemia, drugs, e.g. beta blockers) or by using a positive inotrope, which may be defined as an agent that increases the gradient of the stroke work to filling pressure relationship, resulting in a larger stroke volume for the same pre- and afterload pressures. When considering the use of an inotropic agent (see **Table 24.2**), the adverse effects of vasoactive agents on ventricular efficiency, metabolic rate and regional distribution of flow should be considered.

HEART RATE AND RHYTHM

In cardiac failure the stroke volume is usually constant for rates up to 100/min and thereafter falls as restriction of diastolic filling time limits end-diastolic volume. Increasing the heart rate from 70 to 90/min will increase CO by almost 30%. Achieving this with a chronotrope such as the β_1-agonist isoprotenerol (isoprenaline) increases myocardial work and oxygen consumption and also ventricular irritability. In patients with ischaemic heart disease and particularly after a recent myocardial infarction, atrial or atrioventricular sequential pacing (which maintains coordinated atrial contraction in heart block) improves haemodynamics without stimulating myocardial metabolism and increasing myocardial irritability.[37]

Heart rates above 110/min, particularly with an irregular rhythm, should be controlled by either drugs or DC cardioversion after ensuring that plasma potassium and magnesium levels have been corrected. If the rhythm is supraventricular and unstable with intermittent periods of sinus rhythm, pharmacological control is indicated using either digoxin or amiodarone. Digoxin is appropriate for atrial fibrillation and has a temporary positive inotropic effect.[38] However, amiodarone is suitable for all supraventricular rhythms and is more likely to restore sinus rhythm. A meta-analysis showed that, used prophylactically, it reduced the rate of arrhythmic episodes and sudden death in patients with recent myocardial infarction or congestive cardiac failure.[39] It is, however, a negative inotrope and this can be significant in the patient with severe heart failure.

A fixed rate of 150/min suggests atrial flutter and should prompt careful inspection of the ECG and a trial of adenosine. A persistent sinus tachycardia unexplained by fever may be due to hypovolaemia, pain or anxiety.

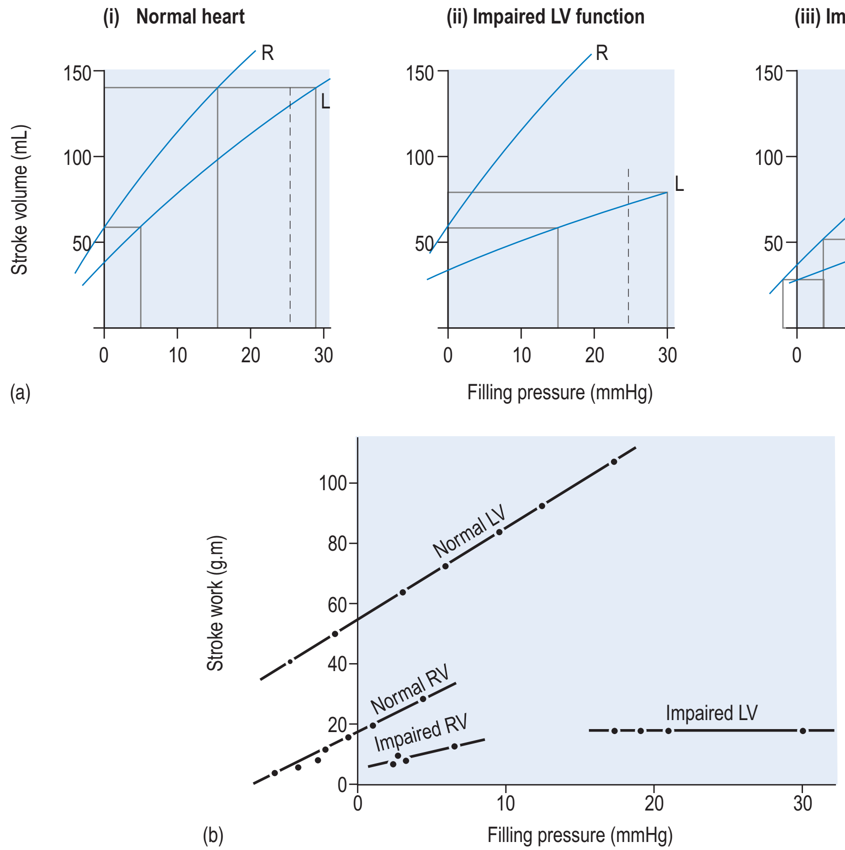

Figure 24.3 Ventricular function curves: (a) relationship between stroke volume (ml) and atrial filling pressure for left (L) and right (R) ventricles in patients with normal and impaired ventricular function; (b) relationship between stroke work (g.m) and atrial filling pressure (in mmHg) for the left (L) and right (R) ventricles for a normal subject and a patient with severe left and right ventricular failure.

ASSESSMENT OF MYOCARDIAL FUNCTION

Of the six key circulatory variables that define ventricular function, three (RAP, MAP and HR) can be assessed clinically and are routinely monitored in ICU patients. However, additional monitoring, traditionally using the PA catheter, is required to *measure* the other three variables (LAP, PAP and Q_t) in order to answer the following questions:

1. Is further intravascular volume indicated?
2. Is CO too low and compromising global oxygen delivery?
3. Is dilator, constrictor or inotropic therapy appropriate?

It is certainly not always necessary to use invasive monitoring. Initial management can be based on clinical assessment of intravascular volume and CO. The discipline of committing to an estimate of these key variables ensures that both the analysis of the circulation and the approach to treatment are logical. Further monitoring should be instituted if the initial management does not produce clinical improvement. Alternative, less invasive methods are available for assessing CO such as oesophageal Doppler,[40] lithium dilution,[41] continuous CO by pulse contour analysis (PiCCO) and echocardiography[7] – techniques that can also provide data on the volume rather than pressure preload of the left ventricle. **Table 24.3** lists some features of the techniques available for measuring cardiac output and whether they provide information on left ventricular preload. Further details of circulatory monitoring and these other techniques are described in the section on haemodynamic monitoring (see Ch. 16). A recent International Consensus Conference produced guidelines for the haemodynamic monitoring and management of patients with shock.[42]

KEY POINTS WHEN ASSESSING CARDIAC FUNCTION

- Pressure is no guarantee of flow.
- Trends and changes are more important than a single observation.

Table 24.3 Comparison of methods for assessing cardiac output

METHOD	INVASION/RISK	VENTRICULAR PRELOAD ASSESSED	COMPLEXITY	MEASUREMENT ERROR	COST
Indicator dilution					
Thermodilution (using PA catheter)	+++	From 'wedge' pressure	++	+	++
Fick	+++	No	+++	+	++
Indocyanine green	+++	No	++	+	++
Lithium	++	Yes	+	+	+
Respired gas					
Modified Fick	+	No	++	++	+
Inert gas rebreathing	+	Yes	+++	++	+
Doppler (oesophageal)	+	Yes	++	++	+++
Echocardiography	0	Yes	++	+++	+
Impedance cardiography	0	No	++	++	+
Pulse contour analysis	+	Yes (ITBV)	+	++	+
Clinical assessment	0	Yes	+	++	0

- Dynamic tests (e.g. assessing stroke volume response or a change in pulse pressure or stroke volume variation to a fluid challenge) are more revealing than static tests (e.g. central venous pressure, MAP).
- Monitoring devices may be complex with many potential sources of error, e.g. 'blocked' catheters, failure to re-level the transducer after a change in the patient's position. Readings should always be interpreted with care and in conjunction with clinical assessment.
- Invasive monitoring has its own hazards (infection, trauma, immobility) and should be removed if no longer required.

PULMONARY ARTERY CATHETERISATION

This remains a widely used method for measurement of left atrial and PA pressures and assessment of CO using the thermodilution technique. Although generally viewed as the 'gold standard' for determining CO, the error is at least 10%, even with fastidious attention to technical detail.

Inflation of the balloon at the end of the catheter provides a PA occlusion pressure (or pulmonary capillary wedge pressure), which reflects left atrial pressure provided there are no significant pulmonary vascular bed abnormalities, as occur in chronic obstructive airways disease and long-standing mitral valve disease. Despite obtaining a good-quality wedge tracing, the measurement must be interpreted with caution since increased intrathoracic pressure and diastolic dysfunction make this pressure measurement an unreliable index of true left ventricular volume preload.

The focus on 'goal-directed therapy' led to the widespread use of PA catheters, but their indiscriminate use was challenged by a multicentre case-controlled study suggesting that patients managed with a PA catheter had a poorer outcome than those managed without such intervention.[43] This study probably reflected the enthusiasm for inappropriate goal-directed therapy prevalent at that time, poor training in the use of the catheter and an inability of clinicians to respond appropriately to the data obtained.[44] More recent evidence suggests neither harm nor benefit with the use of a PA catheter and a risk–benefit assessment should be made on an individual patient basis prior to its use.

Box 24.4 lists the indications for PA catheterisation in heart failure. Other aspects of haemodynamic monitoring are discussed in Chapter 16.

Box 24.4 Indications for pulmonary arterial catheterisation in patients with heart failure

Failure to improve with initial circulatory management and uncertainty about adequacy of cardiac output and relationship between atrial filling pressures

Assessment of left ventricular preload when the relationship between right and left atrial pressures is uncertain owing to recent myocardial infarction, valvular abnormalities or high pulmonary vascular resistance. A low wedge pressure indicates that further volume is indicated, but a high value does not necessarily exclude the need for further volume

Measurement of cardiac output by thermodilution to direct appropriate choice of vasoactive drug and to manipulate therapy, particularly when high doses are being used

Need to monitor pulmonary arterial pressures and assess right ventricular function

ASSESSMENT OF INTRAVASCULAR VOLUME STATUS

CLINICAL

This is conventionally based on measurement of the right atrial filling pressure and the assumption that a normal relationship exists between the atrial filling pressures, which is not necessarily valid in the critically ill patient particularly in cardiogenic shock. Although values < 12 mmHg suggest hypovolaemia, higher levels are more difficult to interpret particularly in the ventilated patient. The RAP should therefore be interpreted carefully and in light of other clinical evidence. However, such static tests for assessing the intravascular volume are less valuable than dynamic tests, such as the fluid challenge and the effect of positive-pressure ventilation, which assess the circulatory response to an intervention.

Intravascular volume depletion is suggested if hypotension is precipitated by sedation, analgesia and postural change. In the patient receiving positive-pressure ventilation, respiratory fluctuation in the arterial pressure tracing also suggests relative hypovolaemia. This is confirmed if brief disconnection from the ventilator causes the blood pressure to rise and venous pressure to fall; the measurement off the ventilator more accurately reflects the ventricular end-diastolic *transmural* pressure. This manoeuvre is relatively contraindicated in patients with acute respiratory distress syndrome as loss of positive end-expiratory pressure may cause widespread alveolar collapse.

FLUID CHALLENGE

If hypovolaemia is suspected, a fluid challenge should be administered and the impact on blood pressure, flow and preload observed. In the volume-depleted patient blood pressure and flow will increase with only a small, transient increase in filling pressure. While pulmonary gas exchange remains satisfactory there is less anxiety about giving further fluid. Sufficient volume will have been given when either the target pressures are achieved and the evidence of poor peripheral perfusion and organ dysfunction has resolved, or when there is a sustained rise in filling pressures to a level above which there is a risk of pulmonary oedema developing. An objective assessment of the effect of such a fluid challenge can also be made by looking for a ≥ 10% rise in stroke volume.

Deciding the appropriate fluid volume to give in sepsis can be difficult and frequently represents a balance between giving sufficient volume to prevent the use of excessive doses of constricting inotropes and giving excessive amounts with consequent tissue oedema and deterioration in pulmonary gas exchange.

If there is concern about administering a fluid challenge, an assessment of fluid responsiveness in critically ill patients can be made by passive leg raising; the legs are elevated to 45° from the horizontal resulting in a reversible fluid challenge as venous blood is diverted to the central circulation (Trendelenberg positioning of the bed may also be used to simulate this manoeuvre).

VALSALVA MANOEUVRE

The effect of changes in intrathoracic pressure can be used to assess intrathoracic blood volume and provide an estimate of true left ventricular preload. **Figure 24.4** shows the classic Valsalva response in a normal subject and in a patient with a high intrathoracic blood volume. If a normal-type trace is observed on the monitor, further volume is indicated, whereas a square-wave response indicates an adequate left ventricular volume preload.[45] This response can be quantified by calculating the ratio of the pulse pressure during phase 2 of the manoeuvre to the baseline value. This correlates with measurements of pulmonary capillary wedge pressure[46] and can be applied at the bedside in sedated, ventilated patients.[47] However, if the patient is breathing spontaneously, this test is difficult both to perform and to interpret.

ECHOCARDIOGRAPHY

Echocardiography is useful in identifying inadequate volume preload and the need for further fluid resuscitation, particularly when the preload pressures are high, as may occur with diastolic dysfunction. Performing serial studies to assess the response to therapy (fluid challenge, starting vasoactive therapy, changing ventilator settings) can be particularly valuable.

MANAGEMENT OF CARDIAC FUNCTION IN THE CRITICALLY ILL

Circulatory management should be regularly reviewed in the critically ill patient. Following initial assessment and with knowledge of the primary diagnosis, the need for extra monitoring should be decided, provisional targets should be set for fluid balance, ventricular preload, mean and diastolic arterial pressures and a management plan agreed on how to achieve these goals. Generally a MAP > 65 mmHg with diastolic pressure > 50 mmHg is acceptable but adequate cerebral, coronary, splanchnic and renal perfusion may require higher pressures, particularly in the elderly patient with pre-existing hypertension or widespread atheroma.

CORRECTION OF METABOLIC FACTORS

The following metabolic factors should be promptly corrected:

- *hypoxaemia:* PO_2 < 8 kPa
- *acidaemia:* pH < 7.20
- *hyperkalaemia:* K^+ > 5.5 mmol/L

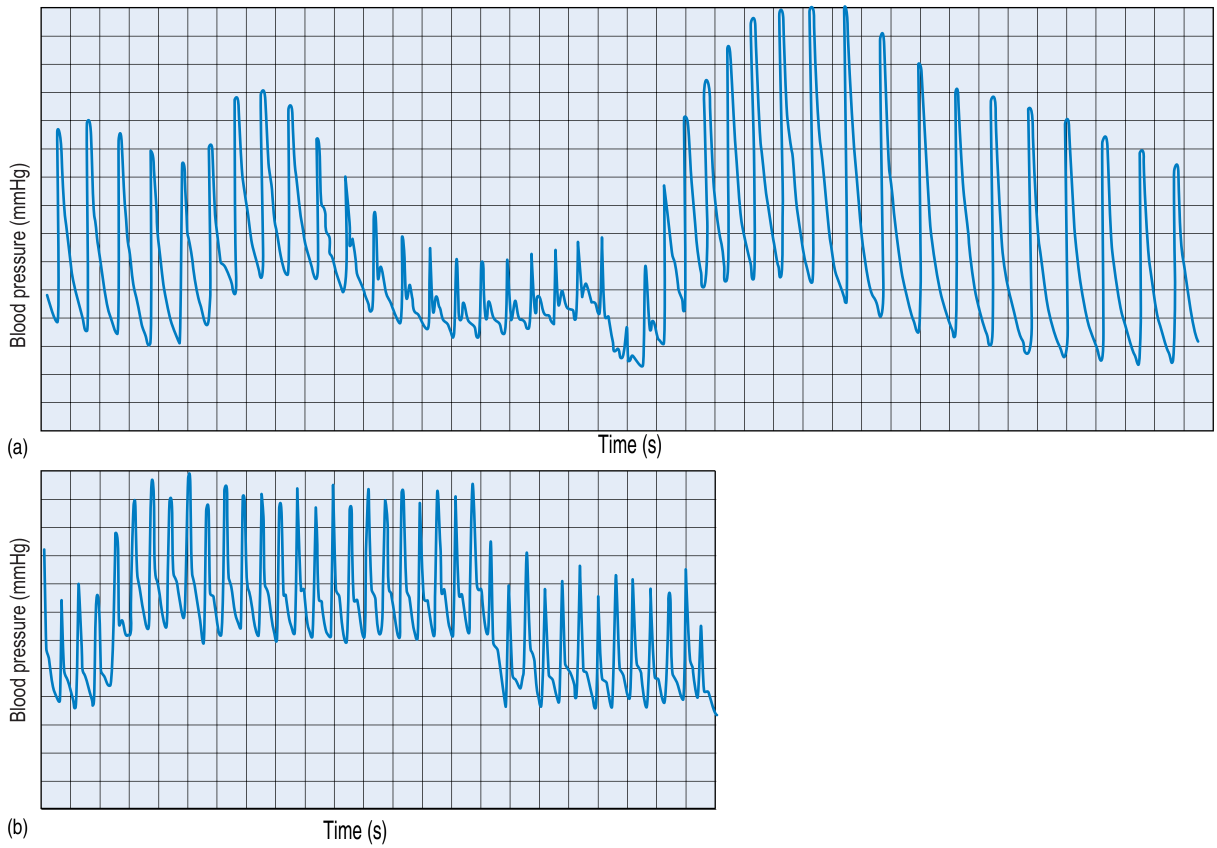

Figure 24.4 Valsalva traces (arterial waveforms): the Valsalva manoeuvre is performed by applying a pressure of at least 30 mmHg (judged from an RA trace) for 12–15 seconds. (a) Normal pulse pressure response. (b) Square-wave pulse pressure response.

- *hypomagnesaemia:* Mg^{2+}<0.9 mmol/L
- *hypocalcaemia:* ionised Ca^{2+}<1.0 mmol/L
- *hypophosphataemia:* PO_4^-<0.8 mmol/L
- *anaemia:* Hb<90 g/L
- *thiamine deficiency:* malnutrition, excess alcohol, diuretic or digoxin treatment.

Metabolic acidaemia with pH<7.20 or base deficit >10 mmol/L should be corrected since myocardial contractility increases linearly with rising pH to values >7.40. The suggestion that sodium bicarbonate should not be used as it produces a damaging paradoxical intracellular acidosis is misleading since the experiments demonstrating this effect were performed in vitro using non-physiological solutions, within a closed system that allowed no correction for any rise in carbon dioxide concentration and in which the sodium bicarbonate was given by bolus rather than by slow infusion.[48] The case for using bicarbonate to correct a metabolic acidaemia in the clinical setting has been recognised[49] and is supported by studies looking at the use of bicarbonate rather than lactate as the buffer solution in haemofiltration.[50] **Figure 24.5** shows the effect of correcting a severe metabolic acidaemia on CO by changing from lactate to bicarbonate haemofiltration.

Although a prospective randomised study demonstrated an improved survival for critically patients if haemoglobin concentration was maintained at 70–90 g/L rather than at 100–120 g/L, this did not apply to the elderly and those with coronary artery disease, in whom the haemoglobin level should be maintained >90 g/L.[51]

Patients with poor dietary thiamine (vitamin B1) intake, chronic alcohol abuse and those on chronic furosemide or digoxin therapy are at risk of thiamine deficiency, resulting in impaired myocardial function. Oral thiamine improves left ventricular function in these patients.[52,53]

SELECTION OF APPROPRIATE VASOACTIVE AGENTS (SEE)

The choice of vasoactive agent when treating acute heart failure represents a balance between the global

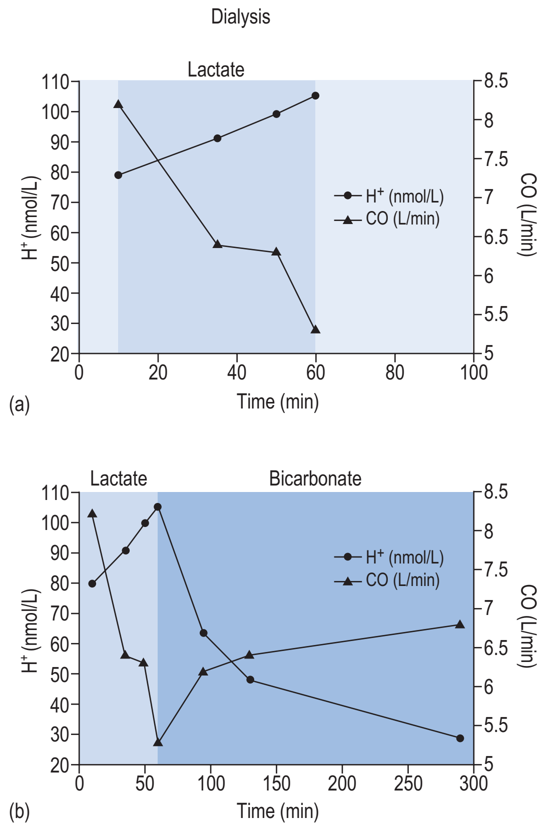

Figure 24.5 Effect of dialysis: (a) rising hydrogen ions and falling CO with lactate buffer dialysis; (b) change to bicarbonate buffer – there is falling hydrogen ion concentration and a rising cardiac output.

circulatory requirements and those of a stressed myocardium. The properties of commonly used agents are shown in **Table 24.2**.

The impact of these drugs in individual patients will be influenced by the *baseline state of the circulation*, i.e. if either intensely constricted or dilated, the same drug will potentially produce different effects on pressure, flow and its distribution. The initial choice of vasoactive agent will depend on the MAP, CO and derived systemic vascular resistance (SVR). For example:

- *CO and MAP are both low with a high SVR:* an inotropic and dilating (inodilator) effect is required and dobutamine or milrinone would be appropriate. Levosimendan would also be a suitable choice in this setting. If CO rises but MAP falls, as may happen with dobutamine, milrinone and levosimendan, and a more powerful inotropic effect is required, epinephrine (adrenaline) may be appropriate. However, increasing doses of epinephrine risk myocardial ischaemia, ventricular irritability, splanchnic ischaemia and the development of hyperlactataemia.[54] Consequently, it may be more appropriate to use norepinephrine (noradrenaline) to maintain MAP when inodilating drugs are being administered.
- *MAP and SVR are low with high CO:* this is frequently seen in sepsis: arteriolar constriction with norepinephrine (noradrenaline) is indicated after adequate volume resuscitation.
- *MAP is at or above target but CO is low with raised SVR:* a dilating agent (nitrate, e.g. glyceryl trinitrate) or an inodilator is appropriate.

When pulmonary vascular resistance and RAP are acutely raised, a pulmonary vasodilator to offload the right ventricle and maintain CO is required but hypotension may result from concomitant systemic arteriolar dilatation and hypoxaemia can develop owing to increased ventilation–perfusion mismatch.

Dopamine has been widely used in the erroneous belief that it selectively improves renal blood flow. However, if the patient has been fully volume resuscitated and a modest inotropic effect with only a small increase in SVR and a natriuretic effect are required, then a low-dose dopamine infusion (<5 μg/kg/min) may be considered.[55] A recent randomised controlled trial demonstrated a greater number of adverse events with the use of dopamine compared with norepinephrine (noradrenaline) in patients with shock. Moreover, in a predefined sub-group of patients with cardiogenic shock mortality was higher in patients treated with dopamine.[56]

Dopexamine is used to improve splanchnic blood flow but, despite reported benefits when used with volume loading in perioperative patients,[57,58] there is little evidence of outcome benefit in established shock.

Patients with chronic heart failure and those receiving long-term beta-agonist infusion often develop tolerance with reduced catecholamine receptor responsiveness, resulting in less effect in raising intracellular cyclic adenosine monophosphate (cAMP) levels and increasing myocardial contractility. Phosphodiesterase inhibitors (milrinone, enoximone) offer an alternative strategy. Milrinone competitively inhibits the phosphodiesterase III isoenzyme, responsible for the breakdown of cAMP, thereby increasing intracellular cAMP levels and improving myocardial contractility independent of β-receptor stimulation. There is also improvement in ventricular diastolic relaxation and a reduction in pulmonary vascular resistance. However, these agents are powerful vasodilators and hypotension frequently limits their use or requires a norepinephrine infusion.

Levosimendan is an intracellular calcium sensitiser and thus bypasses the receptors through which other inotropic agents act. It binds to and sensitises cTnC to calcium without raising intracellular calcium, thus improving cardiac performance and contractility during systole without impairing ventricular relaxation during diastole. Administered as a continuous infusion

(0.1 μg/kg/min) over 24 hours, it has a long-lasting, pharmacologically active metabolite, which results in any improvement in myocardial contractility being sustained for several days.[59,60] Levosimendan also causes vasodilation of vascular smooth muscle due to its action on adenosine triphosphate (ATP)-sensitive potassium channels found in the myocardium, peripheral blood vessels and coronary arteries. Consequently, dose-dependent hypotension may occur although the reduction in preload and afterload and improved coronary blood flow will be beneficial to the failing heart. In the patient with severe heart failure already on inotropic drugs, treatment should start with a low-dose infusion (0.05 μg/kg/min) and no loading dose should be given. Levosimendan may be used concomitantly with beta blockers owing to its site of action, which does not involve beta-adrenergic receptors. Its role in severe acutely decompensated heart failure and cardiogenic shock following acute myocardial infarction appears promising; however, levosimendan remains unlicensed in several countries worldwide and the available evidence to date does not consistently confirm a significant mortality benefit.[61–63]

BETA BLOCKADE

Several studies have demonstrated a reduction in mortality and number of hospitalisations in patients with chronic heart failure treated with beta blockers.[64–66] Furthermore, large studies have demonstrated their benefit early after acute myocardial infarction.[67] Conversely, there is conflicting evidence regarding the perioperative role of beta blockers, and their use should be limited to high-risk patients in order to minimise adverse events.[68]

Although beta blockers are usually commenced in stable patients with heart failure, there is good evidence that they may be safely initiated in patients recovering from recent decompensation or in fact continued at a reduced dose during an episode of decompensation.[69,70]

If tachycardia develops or persists during an episode of acute decompensated heart failure, it may be appropriate to consider a trial of a beta blocker but it is advisable to start with a small dose of a short-acting drug such as metoprolol or a low-dose esmolol infusion. If this beta-blocker 'challenge' is successful then the beneficial effects will include an increased time for ventricular filling, improved coronary perfusion and reduced myocardial oxygen demand.

MECHANICAL SUPPORT FOR THE HEART

Continuous positive airway pressure (CPAP), non-invasive positive pressure ventilation (NIPPV) and invasive mechanical ventilation are commonly used to provide support for patients with acute cardiogenic pulmonary oedema. A recent systematic review concluded that non-invasive ventilation, in particular CPAP, reduced hospital mortality, endotracheal intubation and ICU length of stay.[71] However, a large randomised controlled trial did not show a mortality benefit with the use of non-invasive ventilation, although the study did show an improvement in symptoms and physiological and metabolic parameters.[72] The benefits result from improved oxygenation and reducing or eliminating the work of breathing, which may account for up to 30% of oxygen consumption.[73] This reduction in oxygen consumption reduces left ventricular workload and alleviates myocardial ischaemia. When instituting invasive mechanical ventilation the clinician must be prepared to give volume and even inotropic or vasopressor support as the sedation and other anaesthetic agents given for intubation will reduce endogenous levels of catecholamines, producing arteriolar and venular dilatation and potentially catastrophic hypotension.

Intra-aortic balloon pump (IABP) counterpulsation is physiologically attractive as it reduces afterload, improves coronary and peripheral circulatory perfusion and decreases cardiac work. This results in a more efficient cardiac performance with improvement in both cardiac output and myocardial oxygenation.[74] A common indication for IABP insertion is cardiogenic shock complicating acute myocardial infarction, however a recent randomised controlled trial has questioned the benefit of the IABP in this setting; the study demonstrated that there was no significant difference in 30-day mortality in the IABP and the no IABP groups.[75] Other indications for IABP support include weaning from cardiopulmonary bypass, high-risk percutaneous coronary intervention (although current evidence does not support the routine insertion of IABP in this setting)[76] and as a 'bridging therapy' to cardiac transplantation. The main absolute contraindications to IABP insertion are moderate-to-severe aortic regurgitation and aortic dissection and complications include limb ischaemia, bleeding and infection.

Extracorporeal membrane oxygenation (ECMO) is a technology that has developed from the cardiopulmonary bypass circuit and in a venoarterial (VA) configuration can provide short-term circulatory support in addition to respiratory support. VA ECMO has been used perioperatively in cardiac surgery, in refractory cardiogenic shock and during cardiopulmonary arrest.[77]

Ventricular assist devices (VADs) are mechanical systems that provide circulatory support for patients with both acute and chronic severe heart failure. Support can be provided for the left ventricle, the right ventricle or both. VADs can temporarily take over myocardial function and are usually indicated only if all other treatment options have been explored and improvement in myocardial function can be anticipated.[78] VADs are currently used as a 'bridge' to myocardial recovery in acute heart failure following cardiac

surgery or recent myocardial infarction, or when there is a realistic prospect of cardiac transplantation. However, with recent advances in VAD technology a role appears to be emerging for these devices as a 'destination therapy', in patients with end-stage chronic heart failure who are not eligible for cardiac transplantation.[79] Complications associated with VADS can be significant and include device failure, bleeding, infection, thromboembolism and stroke.

CARDIOGENIC SHOCK AFTER ACUTE MYOCARDIAL INFARCTION

Cardiogenic shock occurs in 5–10% of patients following acute myocardial infarction and the mortality rate remains significantly high at 50–80% with medical treatment alone.[80] In patients admitted to intensive care with cardiogenic shock, the following additional points should be noted:

- The effects of management on myocardial oxygenation must be considered as well as global circulatory targets.
- Although the patient may be ventilated on ICU, therapies demonstrated to improve myocardial salvage must not be overlooked or delayed. Emphasis should be placed on early revascularisation therapy and patients should undergo urgent coronary angiography to allow angioplasty and stenting if appropriate. The benefits of aspirin are significant if given in the early hours after infarction; if necessary the aspirin can be given rectally. A beta blocker[67] and an ACE inhibitor[81] should be started as soon as clinically possible but bradycardia, heart block, hypotension and impairment of renal function may cause delay. Once stable, patients with left ventricular dysfunction and heart failure should also be started on an aldosterone receptor antagonist such as spironolactone[82] or eplerenone.[83,84]
- In patients admitted following an out-of-hospital cardiorespiratory arrest, therapeutic hypothermia (cooling to 32–34°C) has been shown to be beneficial,[85,86] but if planned this should not prevent other interventions such as primary angioplasty being performed if appropriate. It must also be realised that monitoring the patient is more complex in the hypothermic patient since paralysis is often necessary to prevent shivering, most of the techniques for CO measurement are invalidated and both bedside assessment of the circulation and interpretation of acid–base and lactate data are difficult.
- It is important to recognise:
  - right ventricular infarction (ST elevation in lead V_4R) since further monitoring may be necessary to ensure appropriate volume loading and to direct therapy to offload the right ventricle[87]
  - the development of either a ventricular septal defect or mitral regurgitation from papillary rupture as urgent surgery may be indicated.[88]

PULMONARY HYPERTENSION

Pulmonary hypertension (PH) is a frequently encountered pathophysiological disorder in ICU and is associated with high mortality.[89] **Box 24.5** summarises the most recent clinical classification of PH.[90] The classification splits PH into groups according to underlying cause and therefore likely to have similar treatment

Box 24.5 Clinical classification of pulmonary hypertension[90]

1. Pulmonary arterial hypertension (PAH)
   1.1 Idiopathic
   1.2 Familial
      1.2.1 BMPR2
      1.2.2 ALK1, endoglin (with or without hereditary haemorrhagic telangiectasia)
      1.2.3 Unknown
   1.3 Drug and toxin induced
   1.4 Associated with:
      1.4.1 Connective tissue diseases
      1.4.2 HIV infection
      1.4.3 Portal hypertension
      1.4.4 Congenital heart diseases
      1.4.5 Schistosomiasis
      1.4.6 Chronic haemolytic anemia
   1.5 Persistent pulmonary hypertension of the newborn
1. Pulmonary veno-occlusive disease and/or pulmonary capillary haemangiomatosis
2. Pulmonary hypertension due to left heart disease
   2.1 Systolic dysfunction
   2.2 Diastolic dysfunction
   2.3 Valvular disease
3. Pulmonary hypertension due to lung diseases and/or hypoxia
   3.1 Chronic obstructive pulmonary disease
   3.2 Interstitial lung disease
   3.3 Other pulmonary diseases with mixed restrictive and obstructive pattern
   3.4 Sleep-disordered breathing
   3.5 Alveolar hypoventilation disorders
   3.6 Chronic exposure to high altitude
   3.7 Developmental abnormalities
4. Chronic thromboembolic pulmonary hypertension
5. PH with unclear and/or multifactorial mechanisms
   5.1 Haematological disorders: myeloproliferative disorders, splenectomy
   5.2 Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
   5.3 Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
   5.4 Others: tumoural obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

ALK-1=activin receptor-like kinase 1 gene; PAH=pulmonary arterial hypertension; BMPR2=bone morphogenetic protein receptor type 2; HIV=human immunodeficiency virus.

strategies. An important distinction to note is that group 1 PH or pulmonary arterial hypertension (PAH), previously known as primary pulmonary hypertension, includes a set of disorders where PH is the primary problem. In contrast, all other classification groups are due to conditions that lead to PH as result of cardiac dysfunction, abnormalities in the lung parenchyma, chest wall abnormalities, or mechanical obstruction of the pulmonary vasculature.

PH is defined as a mean pulmonary arterial pressure (mPAP) greater than 25 mmHg on right heart catheterisation whilst the patient is at rest.[91] In the critical care setting, common pathological conditions leading to PH include severe respiratory failure,[92] ARDS,[93] left-sided heart failure leading to increased left atrial pressures,[94] massive pulmonary embolism,[95] mechanical ventilation,[96] and following cardiac and thoracic surgery.[97] The presence of PH in many of these conditions is associated with increased mortality.[93–95,97] In addition several factors including sepsis, cardiac arrhythmias, and treatment failure can precipitate acute exacerbations of chronic PAH leading to ICU admissions. Sepsis in these patients is associated with poor outcome.[98]

Several disorders lead to PH in ICU yet there are no consensus or international guidelines that exist to assist with the management of these patients. Detailed reviews addressing PH[99–101] and PAH[101,102] in the critical care setting fail to make authoritative recommendations mainly as a result of paucity of data. Therefore management of PH relies on extrapolated data from animal studies, surgical patients, local expertise and biological plausibility of interventions.

PATHOPHYSIOLOGY

An understanding of the pathophysiological changes seen in patients with PH is essential to understand the available treatment strategies and the likelihood of their success. Invariably the most crucial manifestation of PH is right ventricular (RV) dysfunction. Under normal conditions RV outflow is to a high-compliance, low-pressure and low-resistance system. The thin-walled RV is highly sensitive to small increases in the pulmonary vascular resistance (PVR) leading to ventricular dilation, an increase in end-systolic volume, and reduced ejection fraction and pulmonary blood flow. This in turn results in a reduction in cardiac output (CO). In the initial stages the RV responds by enhancing contractility in order to maintain CO.[103] Further increases in RV afterload overwhelm these compensatory mechanisms resulting in reduced cardiac output and systemic circulatory failure. The intimate anatomical relationship of the two ventricles sharing a septum and both being bound by tight pericardial fibres leads to interdependence. In the setting of increased afterload the dilated RV loses its normal shape and pushes the septum towards the left ventricle thereby compromising LV filling and output.[104,105] RV dilatation can also lead to tricuspid regurgitation further lowering cardiac output. In addition to these anatomical considerations, fall in systemic blood pressure can compromise RV perfusion thereby leading to ischaemia and further RV dysfunction. Unlike the LV, under normal conditions coronary perfusion to the RV is maintained throughout the cardiac cycle. As RV pressure increases there is a decrease in the perfusion pressure gradient between the aorta and the RV during systole, thereby limiting coronary perfusion mainly to diastole.[106]

CLINICAL ASPECTS

Key to the management of patients with PH is diagnosis of underlying cause and, if feasible, treatment should focus on prompt reversal of the cause. Like most other disorders requiring critical care the maxim of good ICU care is applicable to these patients also. The discussion that follows looks at treatment strategies specific to PH and the associated RV dysfunction.

MONITORING

The gold standard for diagnosing and monitoring PH in the ICU remains the PA catheter. Invasiveness of the procedure and a lack of evidence supporting a benefit in the general ICU population have meant that the use of the PA catheter has declined in the critical care setting.[107,108] Furthermore, the use of PA catheters specifically in PH has not been studied. Echocardiography is increasingly being used in ICU and can provide clinicians with much of the information needed to manage such patients. It has the added benefit of being non-invasive and provides information on RV and LV structure and function, pericardial effusions and tricuspid incompetence.[100] A recent systematic review, however, found only modest correlation between pulmonary pressures determined by echocardiography and those measured by right heart catheterisation.[109] The virtues of echocardiography in PH in ICU populations have not been studied and ultimately local expertise is likely to dictate local practice.

MANAGEMENT

The need for adequate oxygenation applies to most critically ill patients but assumes greater importance in PH. RV myocardial oxygen demands are increased in severe PH and hypoxia may increase PVR by precipitating hypoxic pulmonary vasoconstriction. In many cases mechanical ventilation may be unavoidable; however, it comes at a cost. Positive-pressure ventilation has adverse effects on RV afterload and along with administration of sedatives can further compromise CO. Ventilatory strategies should focus on maintaining adequate oxygenation whilst avoiding high plateau pressures.

Fluid resuscitation of patients with PH is extremely challenging. The RV predominantly relies on adequate filling to maintain cardiac output. Conversely, RV dilation as a consequence of volume overload can lead to inefficiency of RV function and can also encroach into LV filling space. In patients with evidence of RV

overload and septal bowing, aggressive fluid removal should be considered as it may improve cardiac output as a consequence of improved LV filling.

Maintenance of sinus rhythm in these patients will improve RV end-diastolic volume and cardiac output. Where possible cardioversion should be performed in patients with tachyarrhythmias. In those patients where this cannot be achieved the focus should be on rate control to optimise ventricular filling time.

Vasopressors and inotropes

The goal of using vasoactive drugs in patients with RV dysfunction secondary to PH is to maintain an adequate CO whilst avoiding increases in PVR and cardiac arrhythmias. In the face of systemic hypotension norepinephrine, a powerful systemic vasoconstrictor, should be considered in these patients. Improving systemic blood pressure has the additional benefit of improving coronary perfusion. However, norepinephrine also causes pulmonary vasoconstriction. In an animal model of acute PH, administration of norepinephrine restored systemic blood pressure and increased PAP.[110] Overall the effect was to improve both RV contractility and cardiac output. In the same study, animals treated with dobutamine showed a greater improvement in RV contractility in comparison with norepinephrine. The dobutamine treated animals also showed a greater reduction in mPAP. In clinical studies dobutamine has been shown to improve RV performance in ischaemic failure.[111] Evidence from these studies suggest that low-dose dobutamine may be useful in acute PH complicated by RV failure. Increases in myocardial oxygen demand and tachyarrhythmias may preclude dobutamine use in all patients with PH.

In another animal study the use of levosimendan and dobutamine in PH was compared. Improvement in RV contractility was similar after administration of both drugs; of the two agents levosimendan was superior at reducing PVR.[112] Small observational studies in humans have shown a similar trend of improved RV contractility and reduced PVR following administration of levosimendan in patients with cardiogenic shock.[113] In theory, levosimendan appears to be a promising alternative to dobutamine with the additional benefit of PVR reduction without increasing oxygen consumption.

Phosphodiesterase-3 (PDE-3) inhibitors such as milrinone and amrinone have inotropic and vasodilating properties. They can improve cardiac output by reducing PVR and increasing RV contractility. PDE-3 inhibitors have been shown to successfully reduce PVR and improve RV contractility in animal models of pulmonary hypertension[114,115] and in patients undergoing cardiac surgery.[116] Treatment with milrinone may require additional vasopressor support, given its propensity for systemic vasodilatation. Inhaled milrinone has shown promise as a therapy to selectively reduce PVR in heart transplant patients[117] and in an animal model of PH,[118] but its use is currently experimental.

Pulmonary vasodilators

Several pulmonary vasodilators are available and the choice of therapy and route of administration usually depend on the side-effects of the drug and the condition of the patient. Intravenous agents can lead to systemic haemodynamic instability and inhaled vasodilators may be more favourable in the ICU setting.[100]

Inhaled nitric oxide (INO) increases production of cyclic guanosine monophosphate (cGMP) and is a potent pulmonary vasodilator. It results in reversal of hypoxic pulmonary vasoconstriction, reduction in PVR and improved oxygenation. INO has been shown to reduce PVR and improve RV stroke work in postoperative cardiothoracic patients with PH.[119,120] Methaemoglobinaemia, NO_2 production and rebound pulmonary hypertension after abrupt cessation are adverse effects associated with INO use.

Inhaled and intravenous prostaglandins are also used as vasodilators in pulmonary hypertension. Inhaled prostacyclin use is associated with significant reduction in mPAP and improvement in ICU patients with PH.[121] There are, however, considerable associated side-effects in this population. Inhaled iloprost, a synthetic prostacyclin analogue, has been shown to reduce mPAP and improve RV function in PH post cardiopulmonary bypass. There was also a significant reduction in PVR to SVR ratio.[122] In a small single-centre study in post-heart-and-lung-transplant patients, inhaled prostacyclin showed similar efficacy to INO in managing PH.[123]

Phosphodiesterase-5 (PDE-5) inhibitors stop the degradation of cGMP leading to vasodilation. In patients with chronic PAH oral sildenafil, a selective PDE-5 inhibitor, has been shown to reduce mPAP[124] and improve cardiac output by reducing PVR.[125] Sildenafil has also been used as bridge to avoid rebound hypotension following INO withdrawal in post-cardiac-surgery patients.[126] Following haemodynamic stabilisation there may be a role for sildenafil in reducing PVR in the critical care setting.

Mechanical devices

In patients where all other treatment options have been exhausted, lung transplantation may be the only viable option. Case studies have reported the use of RV assist devices in patients with PH. Extracorporeal life support, in the form of veno-arterial extracorporeal membrane oxygenation or pumpless lung assist devices inserted into the pulmonary circulation, has also been described as a bridge to transplantation.[99]

SUMMARY

PH and consequent RV dysfunction are frequently encountered in the ICU with a high associated mortality rate. Prompt identification of the underlying cause and its treatment should be the main focus of management. There is very little evidence for the use of specific treatments in the ICU setting and a 'one-size fits all'

approach is unlikely to work given the varied aetiology. A few general principles such as optimising fluid status, optimising heart rate and rhythm, avoiding high-pressure ventilation, maintaining coronary perfusion by optimising systemic pressure, inotropic support for RV dysfunction, and inhaled pulmonary vasodilation may be applied where appropriate. Choice of individual therapies should be guided by an understanding of their mechanism of action and the expected physiological response in an individual patient. The response should be monitored closely to avoid adverse events and to optimise therapy.

Valvular and congenital heart disease and bacterial endocarditis

Mary White and Susanna Price

Valvular heart disease (VHD) is less common than coronary artery disease, hypertension and heart failure; none the less it remains a significant health care issue worldwide.[1,2] In developing countries rheumatic heart disease (RhHD) predominates; however, over the preceding half century in industrialised nations the predominance of VHD has shifted from a rheumatic to degenerative aetiology.[3] These changes in the burden of VHD have been accompanied by significant developments in interventions, including transcatheter procedures for valve implantation and repair.[4] Additionally, advances in surgical and interventional cardiology techniques have resulted in increasing numbers of patients with congenital heart disease surviving to adulthood.[5] Thus valvular and congenital heart disease are increasingly likely to be present in the critical care patient population, and knowledge of the underlying pathophysiology, clinical presentation and management are important for the intensive care clinician.

GENERAL PRINCIPLES: VALVULAR HEART DISEASE

The prevalence of VHD is 2.5%, increasing significantly with age (<65 years <2%, 66–75 years 8.5%, >75 years 13.2%).[6] The commonest aetiologies are degenerative and rheumatic (RhHD), with others (endocarditis, inflammatory, congenital) accounting for fewer than 10% of cases. Whereas degenerative valve disease predominates in industrialised nations, the prevalence of RhHD remains significant, particularly in the elderly. In developing countries improved socioeconomic conditions together with antibiotic prophylaxis have contributed to the reduction in incidence of rheumatic fever; however, RhHD remains an important cause of mortality and morbidity in young adults, accounting for 350–500 000 deaths per annum in Asia alone.[6] VHD (left-sided) may be a primary cause of intensive care admission, or an incidental finding that may significantly alter management of the critically ill patient. Characteristics of left-sided valve disease are shown in **Table 25.1**.

Right-sided VHD is rarely a cause for critical care admission, and then generally due to associated pathology (i.e. sepsis in endocarditis) rather than the haemodynamic effects of the valve lesion.

Approximately 28% of patients with VHD have had previous valve replacement. Adequate and appropriate anticoagulation is paramount to the management of patients with previous mechanical valve replacement as subtherapeutic anticoagulation, even for 24 hours, may lead to thrombosis presenting as acute cardiovascular collapse. The differential diagnosis is pannus formation, although thrombosis is classically associated with a more acute, severe presentation, and the two may coexist. Current recommendations are for surgical intervention, with thrombolysis being reserved for patients in extremis in whom surgery is contraindicated. Additional considerations include avoidance of bacteraemia, and indwelling cannulae should be removed as soon as possible. When severe heart failure (HF) is diagnosed in any patient with a prosthetic valve, prosthesis malfunction must be presumed until proven otherwise.[7]

Evaluation of VHD includes obtaining a history to determine symptomatology and co-morbidities, and clinical examination to determine the presence/severity of the lesion(s) and associated features. Chest radiography (CXR) and electrocardiography may indicate pulmonary venous/arterial hypertension/congestion, cardiomegaly or conducting system disease/ventricular hypertrophy/associated arrhythmia. Echocardiography remains the key investigation to confirm the diagnosis and severity of VHD, together with the patient's prognosis. Although the features associated with significant VHD are well described in the outpatient population there are challenges when assessing critically ill patients (see Ch. 27). Other investigations are important in risk stratification and planning of patient intervention; however, they are not generally relevant to the ICU patient population.

Postoperative management of VHD is primarily determined by the degree of ventricular dysfunction (both right and left) and pulmonary hypertension (PHT). In long and complex surgery, RV myocardial protection is particularly challenging, and postoperative interventions are directed to managing the RV and pulmonary circulation (see Ch. 26). No assumptions should be made regarding postoperative ventricular function, and where haemodynamics are not optimal postoperatively then repeated expert echocardiography is mandated. Similarly, where there is potential for

Table 25.1 Characteristics of left-sided valve disease in the Euro Heart Survey[1]

VARIABLES	AORTIC STENOSIS (*N*=1197)	AORTIC REGURGITATION (*N*=369)	MITRAL STENOSIS (*N*=336)	MITRAL REGURGITATION (*N*=877)

From Lung B, Baron G, Butchart EG, et al. A prospective survey of patients with valvular heart disease in Europe: the Euro Heart Survey on Valvular Heart Disease. Eur Heart J 2003;24:1231–1243.

coronary artery compromise (i.e. mitral valve/aortic root surgery) where haemodynamic instability occurs there should be a low threshold for imaging the coronary tree. Postoperative haemodynamic assessment should not rely solely upon CO monitoring, but must include repeated physiological echocardiographic studies to determine the effects (beneficial or detrimental) of any intervention. Where standard interventions fail, appropriate and timely referral for mechanical support is paramount (see Ch. 16).

AORTIC VALVE DISEASE: AORTIC STENOSIS (AS)

In AS, obstruction to LV ejection results in development of LV hypertrophy, and eventually dilatation and failure. Coronary artery disease coexists in 30–50% of elderly patients with AS, and may result in disproportionate LV dysfunction.[8] Calcific AS is a chronic, progressive disease with a long latent period during which patients remain asymptomatic. When asymptomatic the 2-year event-free survival rate is 20–50%.[9–12] Once symptoms supervene, 5-year survival falls to 15–50%. Typical symptoms include syncope, dyspnoea and exertional angina. Clinical examination may reveal a slow-rising small volume pulse, LV heave and soft A2. An ejection systolic murmur radiating to the carotids is characteristic, but may be absent in critical AS. Features of secondary PHT may also be present. ECG features are non-specific, but include LVH. CXR may show a normal cardiothoracic ratio, valvular calcification and/or post-stenotic dilatation of the ascending aorta. The diagnosis is confirmed with echocardiography (see Ch. 27).

Patients with severe AS may be admitted to the ICU with haemodynamic instability, or AS may be an incidental finding in a critically ill patient. AS requiring ICU admission is usually severe and may be previously undiagnosed due to the gradual onset of symptoms. Patients may present in a low CO state, this may be related to the onset of arrhythmia, myocardial infarction or a late/misdiagnosis.

MANAGEMENT

AS severe enough to be the primary cause for ICU admission is a mechanical problem, and unless there is a contraindication, the patient requires aortic valve replacement (AVR). If the patient is not a candidate for AVR the prognosis is extremely poor. Here, balloon aortic valvuloplasty (BAV) may be considered in order to improve haemodynamics and as a bridge to definitive intervention.[13] Recently transcatheter aortic valve implantation (TAVI) has been developed for patients in whom conventional surgery is judged too high risk; however, haemodynamic instability is currently considered a relative contraindication.[4]

Supporting the patient with critical AS on the ICU is challenging. Stroke volume/CO are limited, and the potential to develop myocardial ischaemia (due to mismatch of myocardial oxygen supply and demand from the hypertrophied LV) with consequent catastrophic haemodynamic deterioration is high. Positive inotropic

agents will potentially exacerbate this mismatch and may provoke arrhythmias, and pressors may be required to maintain coronary perfusion pressure. Intra-aortic balloon counterpulsation (IABP) may improve coronary artery perfusion and reduce myocardial oxygen consumption, particularly in patients with coexistent coronary artery disease. Vasoactive agents should be used with caution and under close haemodynamic monitoring. Although vasodilators are generally relatively contraindicated in this patient population, they are potentially beneficial where the SVR is high. Atrial fibrillation (AF) is poorly tolerated; electrolyte imbalance should be aggressively corrected, and a low threshold maintained for institution of antiarrhythmic therapy.[14]

AORTIC REGURGITATION

Aortic regurgitation (AR) is generally well tolerated unless of acute onset in the presence of a hypertrophied LV, or very severe. The haemodynamic consequences are of LV volume overload, resulting in high filling pressures and pulmonary oedema, and a low CO state. As with AS, AR as a primary cause of ICU admission is likely to be severe.[15]

Symptoms of long-standing significant AR include fatigue and dyspnoea; however, acute severe AR may occur in patients with minimal prodrome. Clinical findings include tachycardia with a normal/low volume pulse in a patient with a low CO state, together with features of pulmonary oedema. An audible S3 should be expected. As with AS, the classical findings may be absent in catastrophically severe AR, as the pulse may not be collapsing and the early diastolic murmur may be absent owing to its short duration. Features relating to the underlying pathology (dissection/endocarditis) may also be apparent. CXR may show cardiomegaly and pulmonary oedema, and the electrocardiogram features of associated pathology (i.e. LVH in a patient with hypertension and aortic dissection). Unlike AS, severe AR may be well tolerated, and it is key to identify features that suggest that it is the haemodynamic burden of regurgitation that has precipitated the ICU admission. Here echocardiography is diagnostic (see Ch. 27).

Where surgical intervention is considered, the requirement for preoperative coronary angiography should be carefully evaluated, as the risk of vegetation embolisation during catheter manipulation may outweigh the potential benefits. Here coronary CT may be of use. Aortic root abscess should be presumed to be present in patients with aortic endocarditis until proven otherwise. Daily 12-lead ECG and continuous monitoring is required. PR interval, prolongation, increasing QRS duration and/or a change in axis suggest the diagnosis. These patients are at risk of rapid progression to high-grade AV block and temporary pacing may be required pending surgery.[7]

MANAGEMENT

Haemodynamic consequences of severe acute AR relate to low CO state, high LV filling pressures and low coronary perfusion pressure (perfusion of the left coronary system is diastolic), with more severe AR being associated with a worse outcome. Where premature MV closure is identified on echocardiography, performance of emergency surgery reduces mortality from 80% to 20%.[16] Attempts to increase coronary perfusion pressure using pressor agents may simply increase LV afterload, resulting in worsening of regurgitation, and IABP is contraindicated. Vasodilation in an attempt to reduce afterload is generally precluded by the low diastolic pressures. Bradycardia will increase the regurgitant volume (by increasing diastolic duration). Conversely patients may respond to manoeuvres that increase heart rate; however, positively chronotropic agents are often vasodilators and this may limit their utility.[7]

The definitive treatment for AR severe enough to precipitate ICU admission is AVR. In patients with known/suspected endocarditis, sudden deterioration requiring ICU admission should prompt investigations to exclude fistula formation, complete heart block or myocardial infarction secondary to coronary embolism. With aortic root abscess, urgent surgical referral is essential.[17]

Moderate AR is generally well tolerated. Clinical features are usually characteristic and the main concern in ICU is to avoid development of endocarditis. Haemodynamic management should include avoidance of bradycardia and a reduction in afterload whilst maintaining diastolic blood pressure to ensure adequate coronary perfusion pressure.

AORTIC VALVE REPLACEMENT (AVR)

The haemodynamic postoperative management in patients immediately post-AVR generally relates to the underlying ventricular disease rather than the valve itself. Patients at risk of haemodynamic instability in the immediate postoperative ICU course include those with significant LV systolic dysfunction and/or hypertrophy, RV dysfunction and/or PHT. Where haemodynamic instability occurs, it is vital to diagnose the underlying cause and monitor the effects of any interventions, as some may paradoxically worsen the clinical status of the patient (**Table 25.2**).

Anticoagulation and/or antiplatelet agents should be prescribed on an individual patient basis. In all patients post-AVR, the potential for bradyarrhythmias should prompt daily interrogation of their temporary pacing system, together with determination of their underlying rhythm. Appropriate referral for consideration for additional pacing (no underlying rhythm) and/or permanent pacing should be according to local/national guidelines.[18]

Table 25.2 Aortic valve replacement – interventions

	POTENTIAL INTERVENTIONS	NOTES
LV systolic dysfunction	• Positive inotrope(s) • Consider early mechanical circulatory support if indicated	• May be underdiagnosed if over-reliance on EF/FS; long-axis function should be assessed • May be revealed postoperatively due to challenges in myocardial preservation (esp. with coexisting CAD) • Standard referral practice varies internationally but indications exist (INTERMACS)
LV hypertrophy	• Avoidance of positive inotrope(s) • Maintenance of AV synchrony • Low threshold for antiarrhythmic agents	• May increase myocardial *VQ* mismatch • May cause LVOTO and paradoxical fall in CO • Tolerate AF poorly
RV dysfunction	• Standard for RV failure, including positive inotropic agents, RV-protective ventilation, aggressive treatment of causes of increased RV afterload	• May limit CO by causing LVOTO in presence of significant LVH • May be significant, especially in the presence of PHT
Pulmonary hypertension	• Standard for PHT on the ICU: pulmonary vasodilators, avoidance of pulmonary vasoconstrictors	• Systemic application of pulmonary vasodilators may cause significant haemodynamic instability • Pulmonary vasoconstrictors may be unavoidable in presence of significant LVH
Valve malfunction	• Surgical discussion	• Suspect if hyperdynamic ventricle in presence of low-CO state • Care in interpreting echo gradients immediately postoperatively (see Ch.27)
Tamponade	• Surgical discussion with a view to re-exploration	• TTE potentially misleading, TEE indicated (see Ch.27) • Low threshold for surgical re-exploration

EF/FS=ejection fraction/fractional shortening; LVOTO=left ventricular outflow tract obstruction; INTERMACS=Interagency Registry for Mechanically Assisted Circulatory Support.

MITRAL VALVE DISEASE: MITRAL REGURGITATION (MR)

MR results in volume overload of the LV, leading eventually to dilatation and failure, together with PHT and subsequently RV failure. MR is classified as either primary (intrinsic lesion affecting components of the valve apparatus) or secondary/functional (leaflets are structurally normal; MR results from distortion of the subvalvular apparatus, secondary to LV enlargement and remodelling).[7] When MR is the primary indication for ICU admission it is likely to be severe.[19] As sedation and ventilation reduce the severity of MR, it should also be considered as a possible differential in patients who fail to wean from mechanical ventilation.

Acute MR secondary to papillary rupture, infective endocarditis or trauma should be considered in patients presenting with acute pulmonary oedema and/or cardiogenic shock, together with the relevant clinical history. In acute, severe MR the presentation is of a low CO state, with classical clinical features often absent as the murmur may be soft/inaudible. Chronic MR is more common – examination revealing tachycardia, a displaced LV apex, the presence of S3 and a pan-systolic murmur. Echocardiographic features confirm the diagnosis, underlying cause and severity of regurgitation (see Ch. 27).

MANAGEMENT

In the absence of intervention to address the underlying valve lesion, acute MR is poorly tolerated and associated with a dismal prognosis. The estimated all-cause 5-year mortality in severe chronic MR is 22±3%. Predictors of poor outcome include age, AF, MR severity, PHT, LA dilatation, increased LV end-systolic dimensions and a low LV ejection fraction. Management options for severe MR are surgical (repair/replacement) or, where surgery is contraindicated, medical management (or possibly percutaneous mitral repair).[19,20]

There is no randomised controlled trial comparing MV repair and replacement; however, repair has a lower perioperative mortality, improved survival, better preservation of postoperative LV function and lower long-term mortality. Predictors of postoperative outcome are age, AF, preoperative LV function, PHT and reparability of the valve.[21] The timing of surgery in acute severe primary MR remains controversial.

Although papillary muscle rupture requires urgent surgical intervention, typically valve replacement, patients with chordal rupture may be stabilised for 24–48 hours allowing the LV to adapt to the increased volume load.[19] Supportive therapy includes IPPV, IABP, inotropes and vasodilators and renal replacement therapy as indicated.[22] Surgery is indicated in patients with symptomatic severe primary MR (LVEF>30% and LVESD<55 mm, left ventricular end-systolic diameter), and should be considered in those with severe LV dysfunction refractory to medical therapy, with high likelihood of durable repair and low co-morbidity.[7]

Operative mortality in secondary MR is higher than primary, and is associated with a worse long-term prognosis. Severe ischaemic MR is not usually improved by revascularisation alone, and residual regurgitation postoperatively is associated with increased mortality.[23,24] Indications for surgical intervention in severe secondary MR include those with an LVEF>30% undergoing CABG. Surgery should be considered in those who remain symptomatic despite optimal medical therapy (including CRT), and in those where the LVEF<30% with an option for revascularisation and evidence of myocardial viability.[7] In patients with no surgical option and severe secondary MR despite optimal medical therapy, percutaneous intervention may be considered (currently endovascular edge-to-edge repair) in appropriate centres.[7]

In all patients, optimisation of medical therapy is essential, and where HF is present should be in accordance with published guidelines. These include ACE inhibitors, beta blockers, aldosterone antagonists and, where indicated, resynchronisation therapy.[22]

MITRAL STENOSIS

In mitral stenosis (MS) obstruction to LV inflow results in gradual elevation of left atrial pressure, progressive pulmonary venous and arterial hypertension, and subsequent RV failure. The commonest cause worldwide is RhHD; however, rarer causes include systemic lupus erythematosus, left atrial myxoma and severe annular calcification. Rheumatic MS is a chronic progressive disease with a long latent period, and is well tolerated until it becomes severe. ICU admission is usually precipitated by the onset of AF, or any condition that results in an increase in circulating volume (i.e. pregnancy).[25]

Symptoms of MS include exertional dyspnoea, recurrent bronchitis, fatigue and haemoptysis. Clinical features include mitral facies, a small volume pulse (often AF), a parasternal heave, tapping apex, loud S1 with a rumbling mid-diastolic murmur, and palpable (and loud) P2. In a patient in extremis, the mid-diastolic murmur may be absent owing to the low CO state. In the critical care population MS may mimic ARDS (bilateral pulmonary infiltrates and poor gas exchange). The ECG may demonstrate P mitrale, and CXR an enlarged left atrium; however, echocardiography is pivotal to make the diagnosis, grade the severity of stenosis and that of associated PHT and RV dysfunction, together with assessment of other valves that are commonly also involved in the disease process (see Ch. 27).

MANAGEMENT

As with all valvular lesions, where the primary indication for admission to ICU, MS is likely to be severe, and intervention (surgical or transcatheter) should be performed only in those with clinically significant MS (valve area <1.5 cm^2).[26] Percutaneous mitral commissurotomy (PMC) is the procedure of choice when surgery is contraindicated, or as a bridge to surgery in high-risk, critically ill patients. Outcome predictors include age, functional class, PHT and coronary artery disease (CAD). PMC achieves good results in >80% of patients, with a periprocedural mortality of 0.5–4%, haemopericardium 0.5–10%, embolism 0.5–5% and severe MV regurgitation in 2–10%.[27] Surgical options are MV replacement/repair, with an operative mortality of 3–10%. In pregnant patients with MV area <1.5 cm^2, symptomatic MS should be treated with beta blockers and diuretics; however, in cases of persistent dyspnoea or pulmonary artery hypertension despite medical therapy, PMC can be considered after the 20th week in an experienced centre, with anticoagulant therapy in high-risk patients.[28]

All patients with severe MS are at high risk of thrombus formation and those in AF should be anticoagulated with a target INR of 2.5–3. In patients with sinus rhythm, anticoagulation is indicated where there has been prior embolism or a thrombus is present in the LA.[7,29] In patients with less severe MS, symptomatic relief of dyspnoea can be achieved with diuretics and/or long-acting nitrates. Beta blockers or heart-rate-regulating calcium channel blockers can improve exercise tolerance.

MITRAL VALVE REPLACEMENT

Postoperative management of MV surgery is usually uncomplicated; however, there are a number of scenarios that, when present, can be challenging to manage in the postoperative phase (**Box 25.1**).[30]

Box 25.1 Postoperative complications in mitral valve replacement

Valve-related complications	General complications
MV repair	Generalised LV dysfunction
LVOT obstruction (SAM, systolic anterior motion)	Circumflex coronary artery disruption
Acute failure	PHT
MV replacement	RV dysfunction
Para-prosthetic regurgitation	Tamponade
Prosthetic block	

The main challenge post-MV surgery relates to the degree of PHT (which may be fixed) and associated RV dysfunction (exacerbated by cardiopulmonary bypass). Management of the right-sided circulation is discussed in Chapter 26.

ADULT CONGENITAL HEART DISEASE

Adult congenital heart disease (ACHD) is common (8 per 1000 live births).[31] Currently, approximately 90% of children born with heart defects survive to adulthood, and adult patients in the US now outnumber their pediatric counterparts.[32] ACHD is generally classified according to its complexity. In the critically ill population, increasing complexity is associated with higher ICU morbidity and mortality.[33] When considering a patient in the more acute scenarios, ACHD is classified according to the underlying pathophysiology. In all patients, expert input should be sought regarding investigation and management as soon as possible after hospital/ICU admission.

CONGENITAL SHUNT LESIONS

The physiological changes associated with shunts are determined primarily by the size of the defect and alterations in systemic and pulmonary vascular resistance (SVR/ PVR, **Box 25.2**).

ATRIAL SEPTAL DEFECTS

Formation of the atrial septum occurs from the growth and partial reabsorption of two tissue membranes; the septum primum and secundum. The foramen ovale is the opening between the upper and lower limbs of the septum secundum, allowing shunting of blood from the right to left atrium in utero. Immediately postpartum there is functional closure of the foramen ovale, facilitated by a decrease in RA and increase in LA pressure. Subsequently these anatomically fuse to complete the formation of the interatrial septum. In 20–25% of people, there is incomplete fusion resulting in a patent foramen ovale.[31] Although the magnitude of shunt is not usually significant, this may result in paradoxical embolisation and, in the critically ill ventilated patient, right–left shunting may be the cause of disproportionate hypoxaemia.

Other abnormalities of atrial septation result in a range of defects, the commonest being secundum ASD, which is more frequently seen in females and occurs in 20% patients with trisomy 21. Other variants include involvement of the superior vena cava (superior sinus venosus defect), inferior vena cava (inferior sinus venosus defect) and/or abnormal pulmonary venous drainage. Primum ASDs may be associated with abnormalities of the atrio-ventricular valves and ventricular septal defects (AVSD). Flow across the defect occurs in both systole and diastole, with a predominant left–right shunt in adults. Patients with a significant ASD exhibit signs and symptoms of biatrial volume and RV overload; however, the direction and magnitude of the shunt are variable and age-dependent. In all patients, there may be PHT of a severity independent of the volume of shunt.

Box 25.2 Shunts

Left–right shunt	Right–left shunt
Atrial septal defect	*Tetralogy of Fallot
Ventricular septal defect	*Transposition of great vessels
Truncus arteriosus	*Double-outlet RV
*Total anomalous pulmonary venous connection	*Single ventricle
ALCAPA	

*Requires interatrial and/or interventricular connections for the patient to survive ex utero.
ALCAPA=anomalous left coronary artery from pulmonary artery.

VENTRICULAR SEPTAL DEFECTS

Ventricular septal defect (VSD) is the most common form of congenital heart defect in children (20% of CHD), resulting from abnormal ventricular septation. The type of VSD is defined by the anatomical position (perimembranous, muscular, inlet or outlet), the size of shunt and whether there is resistance to flow between the two chambers (restrictive).[34]

In patients with a VSD, blood flow has two possible pathways: through the usual outflow tract of that ventricle or across the defect to the outflow tract of the other ventricle. Thus, the direction and volume of flow across a VSD is dependent on:

- *relative resistance of each pathway*
- *size of VSD:* the smaller the defect, the higher is the resistance, limiting the interventricular shunt. Conversely in a large, non-restrictive VSD with normal PVR, the sum of resistors from LV to pulmonary artery is very low compared with resistance to flow across the defect, resulting in significant left–right systolic flow across the VSD
- *elevation of PVR in the presence of a large VSD:* the sum of the resistors may approximate the aortic resistance and net shunting will be minimal
- *pulmonary resistance higher than systemic resistance:* the shunt will be right–left regardless of the size of the VSD.

A left–right shunt at ventricular level reduces the LV (and hence cardiac) output by the amount of the shunt. Compensatory mechanisms act to increase intravascular volume until LV end-diastolic volume is sufficient to achieve both a normal CO and the proportionate left–right shunt resulting in a significant LV volume

overload. High LV volume elevates LA filling pressures and may cause pulmonary congestion at rest and/or during exertion. Although the volume of diastolic flow across a VSD is generally minimal, it is an indicator of significant LV disease.

A secondary effect of a larger VSD is the transmission of LV pressure to the pulmonary vascular bed, with the ventricles becoming functionally a common chamber. In the absence of RV obstruction, the pressure in the pulmonary artery equals that in the aorta. The combination of volume and pressure overload contributes to the development of pulmonary vascular disease with reverse shunting (Eisenmenger syndrome).[35]

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus (DA) is an arterial structure connecting the aorta and main pulmonary artery. In utero it allows blood flow from the PA to bypass the non-functioning lungs to return to the placenta via the descending aorta. Usually it closes within 72 hours of birth. If the DA is not completely obliterated, an arterial connection remains between the systemic and pulmonary circulations – patent ductus arteriosus (PDA).

Shunt direction and volume depend on the relative resistance to flow in each direction. In most patients, as systemic resistance is higher than pulmonary, the result is left-to-right flow. The size of the PDA is the principal determinant of the volume of flow. With large PDAs the LV end-diastolic volume must increase to allow the stroke volume to supply both the normal CO and the left-to-right shunt. LA pressures rise and pulmonary venous congestion may limit exertion. There is flow in both diastole and systole and this diastolic flow may result in impaired coronary and splanchnic perfusion.[36]

CONGENITAL OBSTRUCTIVE LESIONS

Under normal conditions the ventricular outflow tracts, semilunar valves and great vessels present no/minimal obstruction to flow. Narrowing of any of these pathways reduces distal flow, and the increase in afterload may result in ventricular hypertrophy, reduced compliance, and higher filling pressures. Symptoms are related to the severity of the obstruction and the side of the heart involved.[37]

INCREASED RV AFTERLOAD

The RV response to increased afterload is to develop hypertrophy and increase systolic pressure. In CHD stenotic lesions are generally well tolerated until they become severe.

Subvalvular pulmonary obstruction in adults is most frequently a residuum of earlier surgical intervention (i.e. for tetralogy of Fallot), but can be found in adult patients with CHD. Severe subvalvular obstruction may rarely present de novo in adults with a double-chambered RV. However, the diagnosis presents most frequently in childhood as a complex that includes the subvalvular muscular obstruction and a perimembranous VSD.

Valvular pulmonary stenosis (PS) is present in 8–10% of patients with CHD. In mild PS (<30 mmHg (4 kPa)), the natural history in patients who have not undergone surgery is indistinguishable from controls. Moderate gradients, whilst well tolerated in children, become more important in adults, possibly owing to progressively decreasing ventricular compliance. More severe obstructive gradients increase RV afterload, resulting in chamber hypertrophy. Clinical presentation of symptomatic patients includes exercise intolerance and arrhythmia.

Supravalvular PS can occur as an isolated abnormality, associated with complex cardiac malformations (i.e. tetralogy of Fallot), fetal teratogenic exposure (i.e. rubella/toxoplasmosis), genetic syndromes (i.e. Noonan's/William's syndromes), or as a result of scarring from previous surgery, including PA banding or arterial switch for transposition of the great arteries. The haemodynamic burden is identical to that of valvular PS.[38]

INCREASED LV AFTERLOAD

Minor degrees of left-sided obstruction are well tolerated; however, when severe, symptoms supervene. There is a tendency for young patients with CHD to under-report symptoms, and a careful history together with objective assessment is important.

Subvalvular AS comprises a spectrum of pathologies affecting the LV outflow tract ranging from a discrete subaortic membrane to hypertrophic cardiomyopathy. Regardless of the presenting anatomical features, each of these lesions tends to be progressive during childhood. The principal effect is increased ventricular afterload, with potential hypertrophy, arrhythmia, reduced chamber compliance and pulmonary venous congestion.

Coarctation is a congenital narrowing of the aorta, accounting for 5–8% of CHD. The obstruction classically occurs just distal to the origin of the left subclavian artery (site of the previous DA). This fixed obstruction, together with maintenance of flow, results in significant proximal hypertension. Over time, alternate pathways develop between the ascending and descending aorta (collaterals), resulting in the classical CXR finding of rib notching. Significant collaterals may mask the severity of obstruction. Coarctation is associated with a bicuspid valve in 50–85% of patients.[39]

ICU MANAGEMENT OF PATIENTS WITH ACHD

Although the principles of resuscitation in this patient population generally differ little from those with acquired heart disease, management of the acutely

unwell ACHD patient is challenging, presenting potential pitfalls in examination, assessment and intervention. Expert advice should be sought at the earliest opportunity. The most common acute presentations are arrhythmia, HF and endocarditis. The main principles guiding ICU management of these patients are to understand:

- the cardiopulmonary anatomy – including any previous interventions: knowledge of the primary lesion, subsequent surgery/interventions and presence of residual haemodynamic lesions (dynamic/fixed)
- the normal physiology – including haemoglobin/haematocrit, oxygen saturation, systemic and pulmonary blood pressure and 12-lead ECG
- how supportive and therapeutic interventions might affect the circulation (beneficial and/or detrimental)
- the specific reason for deterioration/admission.

Common pathologies associated with ACHD that may impact on ICU care are outlined in **Table 25.3**.

In addition, many tenets of critical care management may be particularly harmful in this patient population and should be applied carefully, including volume loading, sedation, positive-pressure ventilation, normal parameters for transfusion and oxygen supplementation. Although the ICU management of such patients is highly specialised, certain presentations merit particular consideration, as they occur relatively frequently in

Table 25.3 Pathologies associated with ACHD

CARDIOVASCULAR	PULMONARY	GASTROINTESTINAL/RENAL/ENDOCRINE
ABSENT OR ABNORMAL CONNECTIONS	INTUBATION	ASSOCIATED ANATOMICAL DEFECTS
• Expected (Fontan/TCPC total cavopulmonary connection) • Unexpected (LSVC left superior caval vein)	• Craniofacial abnormalities in associated syndromes may complicate	• Associated asplenia • GI or renal malformation
MULTIPLE PREVIOUS CANNULATION	ASSOCIATED CONGENITAL PULMONARY DISEASE	CYANOTIC CONGENITAL HEART DISEASE
• Challenging vascular access	• Hypoplastic lung • Severe congenital V/Q mismatch	• Associated renal impairment common
POTENTIAL/ACTUAL RIGHT–LEFT SHUNTING	LUNG REPERFUSION INJURY POSTOPERATIVELY	ENTERAL FEEDING
• Air filters required on lines	• ARDS/ALI-like picture • Unilateral/bilateral	• Severe RHF may necessitate low feeding rates
CO MEASUREMENT	PULMONARY HYPERTENSION	TOLERANCE TO FLUID LOADING/ RESTRICTION
• Intracardiac shunt may complicate • No PA/R-sided connection • Small aorta may invalidate OD	• May not need treating per se • In presence of an inadequate CO, iNO, PC and sildenafil	• Univentricular circulations require relatively full circulation • Acute RH dilatation may occur (i.e. Ebstein's anomaly)
TRANSVENOUS PACING	TRACHEOSTOMY	LIVER FUNCTION
• No access to RV (i.e. Fontan/TCPC) • ECG interpretation • Atrial re-entry may mimic sinus tachycardia	• Presence of collateral blood vessels, abnormal neck anatomy • Previous cardiac surgery • Phrenic nerve palsy	• Abnormal LFTs common postoperatively and associated with increased mortality • Thyroid function • Commonly abnormal in ACHD
DIFFERENTIAL EFFECTS OF VASOACTIVE DRUGS ON SYSTEMIC/ PULMONARY VASCULATURE	DIFFICULTY WITH VENTILATORY WEANING	HAEMOGLOBIN
• Unpredictable • May affect CO and saturations	• Associated congenital musculoskeletal deformities not uncommon	• Cyanotic ACHD associated with erythrocytosis may necessitate more liberal transfusion policy

the emergency setting. ICU mortality in ACHD medical admissions is high (36% in non-arrhythmia cases). As with the non-ACHD population, where no potentially reversible cause for deterioration exists and there is no prospect of intervention, the appropriateness of ICU admission should be considered.[40]

ARRHYTHMIA

The diagnosis of arrhythmia can be challenging, in particular in patients with massive atrial enlargement. Here, atrial tachycardia may mimic sinus tachycardia, and interrogation of an implanted pacemaker or careful comparison with previous ECGs may be required to make the diagnosis. Cardioversion to a malignant rhythm is not uncommon and, as in some patients there may be no transvenous access to the heart, transcutaneous pacing should be immediately available. Amiodarone is frequently prescribed in ACHD, and thyroid function tests should be performed on the diagnosis of a tachycardia or bradycardia, or hospital admission with decompensation of a previously stable patient.[38]

HEART FAILURE

Causes of HF in the ACHD population include impaired LV and RV function (which may be subpulmonary or systemic), volume overload, arrhythmia, excessive shunt and stenotic lesions. Although the principles of management appear similar to those with acquired heart disease, management of the systemic RV and that of the univentricular heart are particularly challenging, and do differ significantly, thus expert advice should be sought.[38]

HAEMOPTYSIS

Haemoptysis in patients with PHT should always be considered a serious event and early transfer to high-level care should be considered, particularly as the most frequent cause of death is related to inability to protect the airway, rather than blood loss per se. Haemopytsis may be attributed to bronchitis, bleeding diathesis, pulmonary artery rupture, pulmonary embolism, tracheaoesophageal fistula or rupture of aorto-pulmonary collaterals. In Eisenmenger physiology, haemoptysis accounts for up to 15% of deaths. Investigations include: CXR, bronchoscopy, CT angiography and embolisation, which may be life saving.[38]

CYANOTIC ACHD

As these patients have a relatively good prognosis the diagnosis is not a contraindication per se to ICU admission. The physiology reflects the body's response to prolonged cyanosis, and includes a rightward shift in the oxyhaemoglobin dissociation curve, increase in CO and increased haemocrit (erythrocytosis). Routine venesection is not recommended as iron deficiency is common, although it may be considered where there are symptoms/signs of hyperviscosity. Appropriate volume replacement is important to avoid haemodynamic collapse. Clotting abnormalities have been documented, including abnormal PT/PTT and deficiency in factors V, VII, VIIII and IX. When measuring the INR, citrate bottles adjusted for the haemocrit must be used. Thrombocytopenia occurs, but only rarely requires treatment. Renal dysfunction is common and may manifest as proteinuria, hyperuricaemia or renal impairment. Thus, contrast should be used only in patients who are well-hydrated, and the contrast load minimised. Any abnormal neurology, and/or persistent headache in cyanotic ACHD patients, should prompt a high index of suspicion for cerebral abscess/haemorrhage.[38]

INFECTIVE ENDOCARDITIS

If untreated, infective endocarditis (IE) is potentially lethal,[41] accounting for up to 1% of all severe hospital sepsis and carrying a hospital mortality of 33%. Despite advances in diagnostics and medical therapy, the incidence has remained relatively static, possibly owing to increased degenerative valvular disease, intravenous drug abuse, numbers of patients with intravascular devices, exposure to nosocomial disease and an increasing number of patients receiving haemodialysis therapy. Previous invasive procedures are considered more common as a cause than dental procedures and consequently the recommendations for antibiotic prophylaxis have changed. Currently *Staphylococcus aureus* is the commonest causative organism.[41]

CLINICAL PRESENTATION

General malaise, weight loss, night sweats and low-grade fever are reported as common symptoms; however, the clinical presentation is often very non-specific. Clinical signs include splinter haemorrhages in nail beds and conjunctiva, clubbing, splenomegaly, anaemia and signs of embolisation, together with features of valvular dysfunction. Regurgitant murmurs are often present and when in combination with symptoms and signs associated HF are a poor prognostic sign. Additional predictors of poor outcome include: age, prosthetic endocarditis, diabetes mellitus, significant co-morbidity, renal failure, stroke, septic shock, periannular complications, and *S. aureus*/fungal/Gram-negative bacilli as the causative organism. Blood cultures remain the cornerstone of diagnosis, confirmed by expert echocardiography,[42] including transoesophageal echocardiogram (TOE) where indicated (see Ch. 27). Although the Duke criteria are useful for classification, they do not replace clinical judgement.[43] In patients who abuse intravenous drugs, endocarditis with pulmonary embolisation is frequently misdiagnosed as pneumonia. Similarly, in those with prosthetic endocarditis (PVE) associated with significant

left-sided paraprosthetic regurgitation, the resultant infected pulmonary oedema may also be misdiagnosed as pneumonia. Culture-negative endocarditis (clinical, echocardiographic and ECG findings suggestive, but no organisms cultured) should raise the suspicion of previous antimicrobial therapy or fastidious organisms/Q fever as the cause.[43]

MANAGEMENT

Controversy remains regarding timing of antimicrobial therapy, with some suggesting that the results of positive cultures should be awaited prior to initiation of treatment. The commonest community-acquired organism in native valve endocarditis (NVE) is *S. aureus*. Antimicrobial treatment should be according to the ESC/EACTS guidelines, modified according to local knowledge where appropriate.[43]

Surgery is undertaken in approximately half of patients with IE and is indicated in patients with high-risk features that make the possibility of cure with antibiotic treatment unlikely, and who do not have co-morbid conditions or complications that make the prospect of recovery remote. Age per se is not a contraindication. The three main indications for early surgery in endocarditis are HF (commonest and most severe complication), uncontrolled infection (most commonly associated with perivalvular extension/difficult-to-treat organisms), and prevention of embolisation (highest in the first 2 weeks). Unless surgery is contraindicated the presence of any one or more of these features demands early surgical intervention in patients with NVE. Complicated PVE, staphylococcal PVE and PVE occurring early postoperatively are associated with worse prognosis if managed without surgery, and must be managed aggressively.

Intensive care after cardiac surgery

Raymond F Raper

Coronary artery bypass surgery is one of the most frequently undertaken surgical procedures. Because of the prevalence of cardiac disease, cardiac surgery has significant health and economic implications. Intensive care may account for up to 40% of the total hospital costs for these patients and much of the short-term morbidity and mortality is based on perioperative events.

The overall mortality following cardiac surgery is low (approximately 3%). However, this ranges from less than 1% for elective coronary artery bypass grafting to more than 30% for more complicated surgery in patients with significant myocardial dysfunction and associated disorders. Intensive care management following cardiac surgery usually involves a short period of recovery before discharge to the ward. For a small percentage of patients, however, at least potentially remediable complications may require the complete intensive care armamentarium, with a highly significant impact on the intensive care unit (ICU) and hospital budgets and resources.

ORGANISATION

The convergence of large numbers of patients with very similar problems in the cardiac ICU provides an ideal environment for the standardisation of care based on protocols and clinical pathways. One of the traps of postoperative cardiac care is that the sameness of the patients tends to obscure their particularity. Individual patient assessment must carefully address the multisystemic manifestations of cardiovascular and degenerative diseases.

Cardiac surgery involves a continuum of care from presentation to post-discharge management and rehabilitation. The intensive care specialist must be involved in this continuum, rather than functioning in isolation from surgeons, anaesthetists, cardiologists and even family practitioners.

The postoperative stage is largely set by the preoperative and operative phases of management. A component of postoperative management is active participation both in principle and in particular in patient selection and preparation, as well as in the conduct of anaesthesia and surgery. Relevant aspects include suitability and preparation for surgery, advanced care planning and more technical issues such as temperature management, invasive monitoring, haemodynamic management and transport. Movement from the operating theatre to the ICU and later to the ward will appear seamless only if the management systems have been well coordinated in advance.

Changing patterns of practice are resulting in the management of older patients with more co-morbid pathologies. Newer procedures are now being offered to patients previously considered inoperable. Patient and family expectations of surgery are expanding. This, together with greater expectation for regular and detailed communication, will increasingly impact on intensive care practice.

CARDIOVASCULAR MANAGEMENT

The first step in the intensive care management of the newly arrived patient who has undergone cardiac surgery involves a simple transfer of ventilation, monitoring and drug administration from transport to ICU systems. This should be structured to minimise disruption.

- Confirm integrity and position of endotracheal and gastric tubes and intravascular catheters.
- Re-establish mechanical ventilation of both lungs.
- Undertake chest radiography to assess lung expansion, pleural integrity and catheter placement.
- Perform early 12-lead electrocardiography to exclude or identify acute ischaemia.

Management is conveniently dictated by standardised protocols, which should cover investigations, fluid and electrolyte management, vasoactive and other drug administration and mechanical ventilation. Standardisation is probably more important than the particulars of the protocol, which might vary considerably among institutions. Optimal cardiovascular management requires a sound knowledge of normal and abnormal cardiovascular physiology. It also requires an understanding of the haemodynamic changes usually seen in the postoperative patient (**Fig. 26.1**).[1]

MONITORING

Electrocardiography and continuous invasive blood pressure and central venous pressure monitoring are

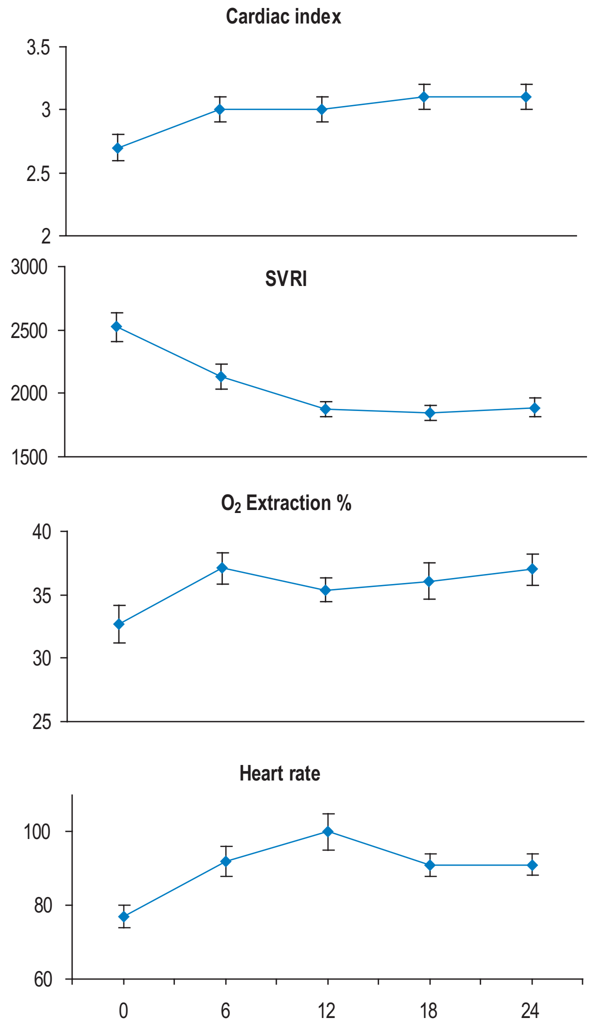

Figure 26.1 Haemodynamic changes following cardiac surgery. SVRI = systemic vascular resistance index.

standard. Flotation pulmonary artery (PA) catheterisation has become somewhat controversial. It is now reasonably well established that PA catheterisation is safe but may not alter outcomes.[2]

- Surgery can be safely undertaken at least in low-risk patients without PA catheterisation.[3]
- Collateral evidence supports PA catheter use in more complicated cases.
- It is essential that the known limitations and complications of PA catheters are considered in usage and interpretation.[4]

Cardiac output measurement by pulse contour analysis and a variety of ultrasound techniques are becoming more commonplace. A precise role for these techniques is not established, especially in the postsurgical patient, where Doppler-enabling windows may be difficult to obtain. Pulse contour analysis is invalid in the presence of intra-aortic counterpulsation. Nevertheless, these techniques and continuous mixed venous saturation monitoring are attractive and very useful in individual patients.

Transoesophageal echocardiography is now almost routine in the operating theatre, at least for more complicated patients. The technique is less suitable for monitoring in the ICU, but is helpful in the diagnosis and management of cardiovascular instability in postoperative patients.

FLUID AND ELECTROLYTE MANAGEMENT

Despite generous intraoperative fluid administration, effective hypovolaemia is common in the early postoperative period, especially as warming with associated vasodilatation occurs.

RESUSCITATION FLUID

- Use of isotonic fluid is essential.
- No benefit for any particular resuscitation fluid has been established. The suggestion that albumin may not be safe has been essentially dispelled.[5]
- Larger volumes of crystalloid than colloid solutions are required.
- An excessively positive fluid balance may increase perioperative complications.

Polyuria is frequently observed in the early postoperative period, possibly related to hypothermia, haemodilution and the after-effects of non-pulsatile cardiopulmonary bypass on stretch and baroreceptors. This usually settles within the first 6 hours, but often necessitates considerable volume replacement in the meantime.

POTASSIUM AND MAGNESIUM HOMEOSTASIS

Hypomagnesaemia and hypokalaemia are frequent in the early postoperative stage. These are exacerbated by polyuria. Late hyperkalaemia is also quite common, especially in patients with renal impairment or prior angiotensin-converting enzyme (ACE) inhibitor administration. Treatment for hyperkalaemia is rarely required in the absence of significant renal impairment. Especially in patients with atrial or ventricular ectopy or tachydysrhythmias, potassium and magnesium levels must be maintained in the high normal range.

Calcium homeostasis is generally not threatened by cardiopulmonary bypass. Massive transfusion, however, frequently causes hypocalcaemia. Ionised calcium levels are now easily monitored by point-of-care blood gas analysers.

HYPOTENSION

Hypotension is both a consequence and a cause of myocardial dysfunction. The major causes include:

- hypovolaemia
- vasodilation

Box 26.1 Low cardiac output

Preload
- Hypovolaemia, including haemorrhage
- Tamponade, pericardial constriction
- Left ventricular diastolic dysfunction
  - Hypertrophy
  - Ischaemia
  - Oedema
  - Hypertrophic or restrictive cardiomyopathy
  - Pulmonary hypertension
  - Right ventricular failure

Afterload
- Excessive vasoconstriction
- Aortic stenosis
- Functional left ventricular obstruction
  - Obstructive cardiomyopathy
  - Systolic anterior motion of the mitral valve

Myocardial function
- Mechanical (ventricular septal defect, valve pathology)
- Cardiomyopathy
- Ischaemia, postischaemic stunning
- Metabolic, electrolyte abnormalities, pharmacological depression

- pericardial tamponade
- heart failure.

Other causes of low cardiac output state (**Box 26.1**) should be considered and excluded. Whatever the cause, hypotension frequently causes myocardial ischaemia and consequent heart failure, especially if it occurs in the first 12–24 hours postoperatively. Angiography during this time almost always shows a significant reduction in the calibre of native coronary arteries, indicating increased coronary resistance and, presumably, altered coronary vasodilator reserve. Treatment of hypotension is urgent if a spiral of ischaemia and heart failure is to be averted.

MANAGEMENT

Successful management of hypotension depends on:

- rapid diagnostic assessment
- diagnosis-specific intervention.

Context is very helpful. Early hypotension in patients with well-preserved ventricular function and no obvious ischaemia usually responds well to fluid administration. Patients with poor ventricular function and increasing inotrope requirement are likely to have a more sinister pathophysiology.

Vasoconstrictors may be useful in breaking the cycle of hypotension–ischaemia–hypotension, but must be used cautiously in patients with impaired ventricular function, and especially in patients with major vascular or aortic pathology, for whom a hypertensive overshoot may be catastrophic.

HYPERTENSION

Complications associated with hypertension include:

- bleeding
- heart failure
- vascular (especially aortic) injury
- myocardial ischaemia.

Significant postoperative hypertension is more common in patients having a history of hypertension and with cessation of beta blockade, but is reasonably common in the early postoperative period. Both absolute pressure and $\mathrm{d}p/\mathrm{d}t$ are important factors in vascular injury. Vascular resistance declines over the first few hours (see Fig. 26.1) so that therapy during this period is best undertaken with agents with a short duration of action. Nitroglycerine is theoretically more appropriate than nitroprusside because of the possibility of coronary steal with the latter agent.[6] In practice, this is almost never apparent and nitroprusside appears to be more effective. Simple measures such as the provision of adequate analgesia and sedation should also be considered.

The target blood pressure varies with the indication. Excessive reduction of blood pressure risks reducing myocardial oxygen supply more than demand. Under most circumstances, a mean arterial pressure between 90 and 100 mmHg (12.0 and 13.5 kPa) seems optimal.[7] Much lower target pressures may be applicable for the management of heart failure or in the presence of a vulnerable aorta, such as occurs with aortic trauma, dissection or aneurysm. Reduction of $\mathrm{d}p/\mathrm{d}t$ with beta blockade is more important than absolute blood pressure control in the management of aortic dissection.

LOW CARDIAC OUTPUT

The aetiology of a low cardiac output following heart surgery is diverse (see Box 26.1). The most common causes include:

- intravascular volume depletion
- systolic heart failure
- pericardial tamponade.

Transient, reversible myocardial depression may follow an episode of acute ischaemia (preoperative or intraoperative) and is especially problematic where intraoperative myocardial protection has been difficult or suboptimal. Recognition of a low-output state in the absence of invasive monitoring may be difficult. Many of the usual signs of low output are also consequences of anaesthesia and surgery. Tachycardia may be obscured by drugs, hypothermia and heart disease, and even lactic acidosis may be an unreliable marker in this patient group.[1]

In the early postoperative period, a relatively low cardiac output may not warrant intervention,

providing tissue oxygen delivery is adequate. Since beta blockade is beneficial in the postoperative cardiac patient, beta agonists should not be used unquestioningly. Nevertheless, optimisation of cardiac function may confer some benefit[8] and intervention is clearly required when tissue oxygen delivery is inadequate.

MANAGEMENT OPTIONS

1. Establish the diagnosis, including aetiology. Distinguishing tamponade from heart failure may require cardiac imaging with transthoracic or transoesophageal echocardiography. This should be the first recourse when uncertainty remains following conventional haemodynamic assessment. Tamponade may not be detectable using transthoracic echocardiography in the early phase after surgery.[9] The principal role of echocardiography is thus the investigation of possible alternative diagnoses.
2. Correct all easily reversible factors, including hypovolaemia, tamponade, acute myocardial ischaemia, electrolyte abnormalities and dysrhythmias.
3. Vasodilators are helpful in the presence of hypertension and ventricular dilatation. Postsurgical vasodilation after the first 4–8 hours often obviates any ongoing role for these agents.
4. Inotropic agents: because of the associated vasodilatation, ino-constricting agents are frequently required, alone or in combination. Issues to consider include:
   - **a.** Dobutamine is an essentially pure β_1-agonist. In the management of acute heart failure, it has been associated with an increase in mortality.[10]
   - **b.** Norepinephrine (noradrenaline) is a potent vasoconstrictor. It is commonly used to manage vasodilation but should probably not be used alone in the presence of a low cardiac output.
   - **c.** Vasopressin has no clearly established role in postoperative cardiac surgery, but does reduce the level of norepinephrine (noradrenaline) required and may thus spare the myocardium from excessive beta stimulation.
   - **d.** Epinephrine (adrenaline) is a potent inoconstrictor but its metabolic effects (especially lactic acidosis) and relative tachycardia make usage in cardiac surgical patients problematic.[11]
   - **e.** Milrinone is a phosphodiesterase inhibitor with a long duration of action and potent vasodilating properties. These make milrinone relatively difficult to introduce and to wean. It has similar haemodynamic effects to dobutamine and is associated with increased atrial fibrillation. Overall benefit is not established.[12] It may be a useful inotropic agent in patients with β-receptor down-regulation.
   - **f.** Levosimendan is a calcium-sensitising agent. It offers little overall benefit in the treatment of heart failure[13] but may be beneficial in the perioperative period.[14]
5. Intra-aortic balloon counterpulsation (IABC; see below).
6. Ventricular assist devices (VAD) are expensive and technically far more demanding than IABC. The refinement of extracorporeal membrane oxygenation (ECMO) circuits has increased their use for short-term cardiac support. When instituted for failure to wean from bypass, the outlook is generally poor.[15,16] Most published VAD data relate to non-surgical patients in whom the role of heart assist devices is increasingly established both as a 'bridge to transplant' and as 'destination therapy'.
7. Delayed sternal closure has an established role in improving outcome after cardiac surgery.[17] Cardiac output is increased and inotropic requirement reduced. Subsequent sternal closure has an acceptably low complication rate. The sternum may be left open following an initial attempt at closure or reopened with later deterioration. Sternal retraction may be required.
8. Mechanical ventilation is generally continued throughout the period of low output. This reduces cardiac workload by removing the work of breathing. Positive intrathoracic pressure reduces left ventricular afterload, which is beneficial to the dilated left ventricle. Positive pressure may be detrimental, however, in the presence of diastolic ventricular dysfunction or hypovolaemia, where the reduction in venous return may further reduce ventricular preload.

INTRA-AORTIC BALLOON COUNTERPULSATION

IABC has an established role in support of cardiac surgery. Its two actions are: (1) augmentation of diastolic coronary perfusion pressure; and (2) left ventricular afterload reduction. This is achieved by balloon inflation (30–50 mL capacity) within the aorta during diastole and rapid deflation of the balloon immediately before aortic valve opening. The catheter is usually inserted using a Seldinger technique, but can be placed by femoral artery cutdown or directly into the descending thoracic aorta. Timing of inflation and deflation is critical to optimal function. This is best achieved using the pressure waveform and a 1:2 ratio (**Fig. 26.2**).

Inflation is timed to coincide with the dicrotic notch. Deflation is timed to occur as late as possible in diastole, ensuring that the IABC end-diastolic pressure is lower than the patient's end-diastolic pressure. IABC increases cardiac index and coronary perfusion and reduces left ventricular filling pressure, myocardial lactate production and oxygen extraction percentage.

Indications for IABC are summarised in **Box 26.2**.

IABC has an established role in the management of reversible myocardial dysfunction especially in the context of myocardial revascularisation (surgical or endovascular). There is a probable benefit in high-risk surgical patients undergoing elective

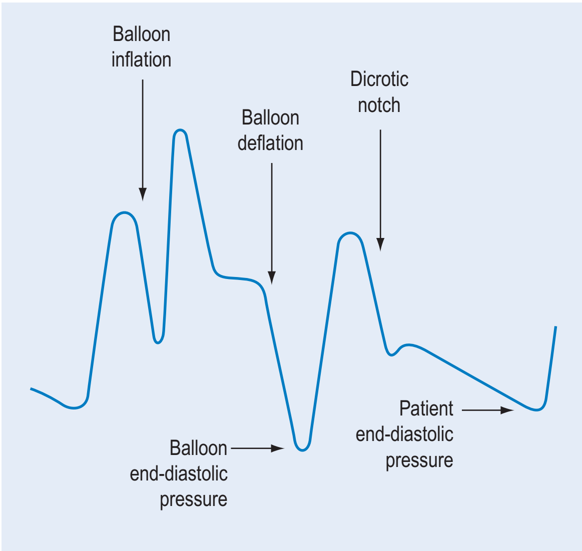

Figure 26.2 Intra-aortic balloon counterpulsation pressure waveform. Inflation is timed to coincide with the dicrotic notch. Deflation is timed to occur as late as possible in diastole, ensuring that the IABC end-diastolic pressure is lower than the patient's end-diastolic pressure.

Box 26.2 Indications for intra-aortic balloon counterpulsation

Prophylactic
- Cardiac surgery
  - Two of: left main >70%, left ventricular ejection fraction <0.4, unstable angina, reoperation
  - Failure to wean from cardiopulmonary bypass
- Non-cardiac procedures in the presence of severe left ventricular impairment, unstable angina

Cardiogenic shock
- *Reversible* myocardial depression
- Support for reperfusion, revascularisation
- Bridge to transplant

revascularisation.[18] IABC is not helpful, however, in the management of cardiogenic shock from irremediable causes except as a bridge to transplant. Complications include:

- limb ischaemia (6–16%)
- vascular trauma, dissection
- infection (cutdown>percutaneous)
- balloon rupture
- bleeding
- thrombocytopenia
- malposition, vascular obstruction
- malfunction, failure to unwrap.

Limb ischaemia is the most frequent complication and optimal management requires early recognition based on routine, systematic observation.

ISCHAEMIA

Postoperative myocardial ischaemia predicts a more complicated course.[19] Recognition is enhanced by automated multilead ST analysis with confirmatory electrocardiography, although diagnosis may be difficult in the presence of preoperative electrocardiographic abnormalities.

Ischaemia may be due to graft failure. Remedial options include coronary angiography and/or reoperation. Angiography offers the potential for tailored reoperation or non-operative intervention. Management decisions may be influenced by surgical factors such as the availability of further conduit and the state of the native arteries. Thus close liaison among ICU personnel, cardiologists and surgeons is essential.

DIASTOLIC DYSFUNCTION

Ventricular hypertrophy is the commonest cause of diastolic dysfunction, and is exacerbated by poor myocardial protection during surgical procedures. Myocardial ischaemia, right ventricular (RV) dilatation and pericardial abnormalities (including tamponade) can also reduce left ventricular volume in spite of elevated filling pressures.[20] Recognition and management can be very difficult.

Diagnosis generally requires:

- demonstration of small ventricular volumes (using echocardiography or other techniques)
- the presence of increased filling pressures.

MANAGEMENT

- Treatable causes should be addressed.
- Blood volume must be maintained, with blood transfusion where necessary.
- Maintenance of sinus rhythm is helpful, if not essential.
- Atrial pacing at an enhanced heart rate is often beneficial since the stroke volume is fixed and the diastolic filling time is already foreshortened.
- β-agonists and milrinone improve diastolic relaxation and hence ventricular compliance.

DYSRHYTHMIAS

Ventricular and supraventricular dysrhythmias are common. Prevention and treatment of electrolyte abnormalities may be prophylactic. New occurrence of complex ventricular dysrhythmias should stimulate a search for causal ischaemia and graft malfunction.

- Ventricular fibrillation and pulseless ventricular tachycardia require rapid defibrillation, preferably before external cardiac massage, which may cause mechanical injury post sternotomy. If haemodynamic stability cannot be rapidly restored, open cardiac massage should be instituted.

- Facilities for atrioventricular pacing are essential as transient heart block is common.

ATRIAL FIBRILLATION (AF)

AF is the most common complication of cardiac surgery.[21,22] Its incidence varies from 10 to 40% in patients undergoing coronary artery surgery and up to 50% with some valvular procedures. Predisposing factors include a history of AF, valvular heart disease (especially mitral valve pathology), increasing age and prolonged P-wave duration. AF can be effectively treated and its recurrence prevented with intraoperative radiofrequency ablation and left atrial reduction during cardiac surgery.[23] There may also be some long-term survival benefit.[24] AF is probably less frequently observed following 'off-pump' surgery, and is most frequently encountered around the second and third postoperative days, but may occur weeks after surgery and hospital discharge.

AF is a potentially serious complication. Apart from discomfort, it may provoke or complicate haemodynamic instability. The major complication of AF, however, is stroke, with an increased risk of approximately threefold. Based on echocardiography, there is the potential for embolic stroke within 3 days of onset of AF.

AF is also associated with:

- increase in inotrope usage
- increased use of IABC
- increased reoperation for bleeding
- prolonged ICU and hospital stay
- increased costs.

Several strategies are beneficial in preventing AF:[25]

- beta blockade
- amiodarone
- sotalol[26]
- diltiazem
- biatrial pacing
- dexamethasone
- colchicine [27]
- statins.[28]

Treatment should be tempered with an understanding that spontaneous reversion to sinus rhythm is frequent. A treatment strategy is summarised in **Box 26.3**.

- Beta blockade is best established.
- Digitalis is not more effective than placebo at reverting AF and may not be helpful in ventricular rate control in the presence of catecholamine stimulation.
- Anti-coagulation should be considered where AF persists for longer than 48 hours and in all cases where elective cardioversion is undertaken.
- Early cardioversion tends to be ineffective and potentially harmful. Although officially recommended in the presence of instability, this is not based on any empirical evidence.

Box 26.3 Management of atrial fibrillation (AF)

Rate control
- Beta blockade
- Calcium channel blockers
- Amiodarone
- Sotalol
- Digitalis

Cardioversion
- Ibuletide
- Amiodarone
- Magnesium
- Electrical cardioversion

Anticoagulation
- Always for elective cardioversion
- Consider if atrial fibrillation persists beyond 48 hours

RIGHT VENTRICULAR DYSFUNCTION

RV failure following cardiac surgery is reasonably common. Aetiological factors include:

- direct RV ischaemia or infarction
- poor myocardial protection
- anteriorly placed RV
- bypass-related pulmonary hypertension.

Management involves:

- volume resuscitation
- maintenance of RV perfusion pressure with vasoconstrictors
- IABC as required
- inotrope administration
- RV afterload reduction.

Useful afterload-reducing agents include nitric oxide, prostaglandins and sildenafil. Conventional vasodilators tend to produce excessive systemic vasodilatation. Occasionally, RV balloon counterpulsation or an RV assist device may be required. Delayed sternal closure has an established role.

EMERGENCY REOPERATION

Emergency resternotomy is indicated as part of resuscitation when haemodynamic stability cannot be rapidly re-established with conventional means.[29,30] Advantages compared with closed-chest resuscitation include:

- establishment of the cause of instability
- correction of the cause (e.g. tamponade, kinked graft)
- more effective cardiac massage
- direct establishment of atrial and ventricular pacing.

Resternotomy also enables the re-establishment of cardiopulmonary bypass and regrafting or correction of mechanical abnormalities as required. Infectious complications of emergency resternotomy are probably increased, but the incidence is not prohibitive.

RESPIRATORY MANAGEMENT

Postoperative mechanical ventilation remains routine in cardiac surgical patients. Immediate extubation appears to offer little patient benefit,[31] but may be expedient. Neither is routine prolongation of ventilation beneficial. Extubation can be safely undertaken with simple protocols. Reintubation is rarely required, but is more likely in older patients with pre-existing lung and vascular disease and impaired ventricular function. Reoperative surgery and bleeding requiring massive transfusion also increase the likelihood of early extubation failure.

Hypoxia is very common in the early postoperative period. It is mostly attributable to atelectasis and responds well to simple measures such as positive end-expiratory pressure (PEEP), prolonged inspiration and simple recruitment manoeuvres. Atelectasis is a consequence of cardiopulmonary bypass and intraoperative ventilation with high inspired oxygen and without PEEP. Long-term sequelae are rare. Incentive spirometry and chest physiotherapy are commonly utilised in the postoperative period, without good supportive evidence. Early mobilisation appears most beneficial. Adequate analgesia facilitates physiotherapy and mobilisation. Non-steroidal agents may increase the risk of complications.[32]

More sinister causes of hypoxia include severe heart failure and hypoxaemic respiratory failure (acute respiratory distress syndrome, ARDS). The aetiology of ARDS is diverse, but includes shock, massive blood product administration and cardiopulmonary bypass itself. Management is not particular to this group of patients. Occasionally, profound hypoxia accompanies minor atelectasis with moderate pulmonary hypertension. Patent foramen ovale (which is seen in 10–15% of the normal population) with right-to-left intracardiac shunt is the likely mechanism.

Clinically detected pulmonary embolism is an uncommon complication of cardiac surgery, probably due to bypass-induced platelet dysfunction, routine postoperative antiplatelet therapy and thromboprophylaxis.[33] Asymptomatic thromboembolism may be significantly more common, however.[34,35] Contrary to earlier beliefs, 'off-pump' surgery may not be associated with an increase in prothrombotic tendency or a need for a more aggressive thromboprophylaxis regimen.[36]

POSTOPERATIVE COMPLICATIONS

BLEEDING AND TRANSFUSION

Excessive postoperative bleeding is a major cause of increased morbidity and mortality. Mechanisms are complex and include preoperative anticoagulation, thrombolysis and antiplatelet therapy as well as activation of haemostatic mechanisms, including fibrinolysis. 'Off-pump' surgery may be associated with excessive bleeding because of administration of anticoagulant and antiplatelet therapy out of fear of early graft closure. There is increasing evidence that transfusion is associated with excessive complications, including death, and that transfusion rates vary amongst institutions.[37]

Most studies of pharmacological strategies to minimise postoperative blood loss have involved preoperative or intraoperative intervention. Extrapolation to the postoperative phase is intuitive rather than established. Aprotinin and the lysine analogues aminocaproic acid and tranexamic acid reduce bleeding and exposure to blood and blood products. Aprotinin has been associated with an increased risk of serious end-organ damage.[38] Desmopressin is probably less effective and has been associated with an increased risk of myocardial infarction.[39]

Effective postoperative measures include reversal of residual heparin (including 'heparin rebound') and correction of coagulopathy with blood products. A systematic approach to operative and postoperative blood conservation, including point-of-care testing to guide therapy, can significantly reduce bleeding and transfusion and resultant complications.[40] Application of PEEP has been shown to be effective in some studies, but not others. Retransfusion of shed blood reduces autologous transfusion requirements without apparent side-effects. Controlled tamponade with discontinuation of drain suction and even clamping of drains has also been reported.[41] Activated factor VII may be effective in controlling bleeding, but may result in increased risk of stroke.[42] Finally, a restrictive transfusion strategy can reduce exposure to transfusion without increased risk.[43]

RENAL FAILURE

Depending on definition and patient groups, acute renal failure is observed in 1–5% of patients undergoing cardiac surgery. Risk factors include increasing age, heart failure, prolonged bypass, diabetes, pre-existing renal impairment and postoperative shock. Surgery without cardiopulmonary bypass may be relatively protective and other potentially modifiable factors include anaemia, blood transfusion and reexploration.[44] Morbidity, mortality and costs are significantly increased. Effective preventive strategies beyond careful haemodynamic management and minimisation of associated nephrotoxic insults have not been established. Nevertheless, attention to urine output in the presence of known risk factors appears warranted.

SHIVERING

Shivering is frequent following cardiac surgery. Mechanisms are complex and not entirely related to core temperature. Shivering causes a significant increase in metabolic rate and hence cardiac workload. This is especially important in the patient with impaired cardiac function and limited reserve. Effective preventive agents include dexamethasone, clonidine, high-dose morphine and external warming. Pethidine and

tramadol effectively reduce the duration of shivering. Short-term neuromuscular blockade is occasionally required.

STERNAL INFECTION

Deep sternal wound infection is uncommon (0.5–2.5%). Associated morbidity and mortality are significant. Risk factors have been variously reported but consistently include diabetes, obesity and use of internal mammary arteries, especially if bilateral. Other contributing factors include prolonged surgery, chronic lung disease, male sex, low postoperative cardiac output, blood transfusion, sternal reopening and dialysis. Close control of blood sugar levels in diabetics[45] and preoperative nasal and oropharyngeal decontamination[46] may help prevent infection.

NEUROLOGICAL COMPLICATIONS

Neurological complications of cardiac surgery include neuropsychiatric deterioration as a consequence of cardiopulmonary bypass, delirium and a range of peripheral neuropathies, the most frequent of which is unilateral phrenic nerve palsy. Paraplegia is a recognised complication of thoracic aortic surgery.

The most devastating neurological complication is cerebral infarction. The incidence varies with patient selection, but ranges from 1 to 5%. The pathophysiology is mostly embolic. Risk factors include carotid artery stenosis, hypertension, AF, aortic atheroma, impaired ventricular function and peripheral vascular disease. 'Off-pump' and especially 'anaortic' surgery (no aortic manipulation) are protective[47] and other operative techniques may also reduce the incidence.

GASTROINTESTINAL COMPLICATIONS

Peptic ulcer disease, pancreatitis, cholecystitis, gut ischaemia, ileus and hepatic dysfunction are uncommon (<1%) after cardiac surgery. Morbidity, however, is quite high. Risk factors include increased age, more complicated surgery and postoperative shock. The incidence of gastrointestinal complications may be reduced with 'off-pump' surgery.

LONG-TERM CONSIDERATIONS

Patients surviving cardiac surgery have a continuing risk of disease progression. It is important that effective secondary prevention strategies be considered or recommenced in the postoperative period. Initiatives with proven long-term benefit in patients with ischaemic heart disease include antiplatelet therapy, beta blockade, ACE inhibitors, lipid-lowering statins and exercise. Treatment for hypertension, diabetes and other intercurrent disorders should also be reinstituted.

A small percentage of patients require long-term ICU management for a variety of complications. Excellent long-term survival and quality of life are possible in this group of patients, especially if the prolonged ICU stay results from pulmonary complications rather than severe heart failure or neurological dysfunction.

Box 26.4 Risk factors for cardiac patients undergoing non-cardiac surgery*

- High-risk surgery (abdominal, thoracic, major vascular)
- History of ischaemic heart disease
- History of congestive heart failure
- History of cerebrovascular disease
- Treatment with insulin
- Renal impairment

*High risk: three or more factors.

NON-CARDIAC SURGERY

Non-cardiac surgery poses a significant risk to the patient with cardiac disease. Postoperative cardiac complications result in significantly increased immediate and late mortality. Simple preoperative assessment enables risk stratification, which might lead to deferment or cancellation of non-essential surgery. Indications for specific investigations and treatments are probably not different in the preoperative patient. However, this might be the first time that a cardiac assessment has been undertaken and hence significant cardiac pathology identified. Risk factors are summarised in **Box 26.4**. Cumulative factors are more than additive. Patients undergoing vascular procedures have a high risk of associated coronary artery disease and should be carefully assessed preoperatively. Perioperative risk can be modified by anaesthetic technique and by optimal medical (or surgical) management of heart disease, which might include myocardial revascularisation.

The principles of postoperative management are the same as those outlined for the cardiac surgical patient. The period of risk for cardiac complications extends for some days after surgery and close monitoring to identify and manage events during this time is desirable in high-risk patients. The immediate perioperative period poses risks associated with anaesthesia, bleeding, fluid and electrolyte imbalance, haemodynamic instability and temperature abnormalities. These can be effectively managed. Early reinstitution of protective treatment (aspirin, beta blockers, ACE inhibition, statins, antihypertensive therapy) may protect against later complications.

Echocardiography in the intensive care unit

Guido Tavazzi and Susanna Price

Historically exclusively the domain of the cardiologist, there has been gradual adoption of echocardiography by other specialties. Transoesophageal echocardiography is now considered mandatory for much of cardiac surgery and is predominantly performed by cardiothoracic anaesthetists. Echocardiography is recommended in international guidelines for investigation of non-traumatic cardiac arrest, and transversal ultrasound is widely used in emergency and trauma medicine.[1] In intensive care, concerns regarding safety of the pulmonary artery catheter, together with development of alternative cardiac output monitoring, and demonstration that echocardiography yields information additional to the pulmonary artery catheter has led to an increase in its use.[2] It is thus inevitable that echocardiography for the assessment and diagnosis of critically ill patients will increase, and therefore intensivists should have knowledge of the principles and limitations of the technique, together with its relevant application(s) in the ICU setting.

PRINCIPLES OF ECHOCARDIOGRAPHY

Ultrasound is generated by application of an alternating current across piezoelectric crystals, the resulting vibration generating a longitudinal wave. The same crystals act as receivers of returning, reflected ultrasound waves, and vibrations induced by these returning waves are used to generate images. Ultrasound can be refracted, reflected and/or attenuated, allowing discrimination between adjacent tissues by virtue of their different acoustic properties. Diagnostic ultrasound frequencies are 1–12 MHz.

Ultrasound is therefore a sound wave comprising longitudinal waves of compression and decompression of the transmitting medium (air/water/soft tissue/blood) travelling at a fixed velocity. As a longitudinal wave, ultrasound is defined by its amplitude, wavelength and cycle duration. One important difference between ultrasound and audible sound is that at higher frequencies ultrasound tends to move in straight lines, and can be reflected and focused. Although some properties differ between ultrasound and audible sound, important principles apply to both. First, the relationship between the wavelength, its velocity and frequency is determined by the equation $\lambda = V/f$, where λ is wavelength, V the velocity of ultrasound through tissues, and f the frequency of the transducer. As V is relatively fixed in soft tissues, the resolution of images is determined by manipulation of the other two factors: a higher frequency probe resulting in a shorter wavelength and better resolution, but at the expense of greater attenuation and reduced penetration. Spatial and temporal resolution determine the image quality, where axial resolution is limited by wavelength, and temporal resolution is determined by frame rate and in turn by the number of pulses/scan line, the number of scan lines/sector and the sector depth and width. Ultrasound is additionally reflected by small objects, and does not propagate easily in gaseous media. This is particularly relevant in echocardiography, as the heart shares the thoracic cavity with the lungs, and thus there are only certain windows where the heart may be visualised.

A number of echocardiographic modalities and techniques are available, and their principles, pitfalls and potential critical care uses are outlined in **Table 27.1**.

PRINCIPLES OF ICU ECHOCARDIOGRAPHY

As with any investigation, ICU echocardiography should be undertaken within existing clinical governance structures, with clear guidelines for infection control/consent/acquisition/storage, reporting and review of images.[4] The imaging technique of choice in the ICU is transthoracic echocardiogram (TTE) unless this is impractical, technically impossible or there is a primary indication for transoesophageal echocardiogram (TOE). Challenges in obtaining adequate TTE views in immobile, ventilated patients are well documented. Here, left-sided contrast can improve the diagnostic yield, even in the hands of inexperienced operators.[5]

TOE should not be performed under sedation in hypoxic patients or those unable to protect their airway. ICU TOE will therefore generally be undertaken in intubated, ventilated patients. Prior to TOE, coagulation and platelet results should be known and correction considered. If oesophageal intubation is difficult and/or coagulation is suboptimal, it should be performed under direct laryngoscopic vision. As patients are often haemodynamically unstable a designated

Table 27.1 Principles and major pitfalls of echocardiographic techniques

DEVELOPMENT	PRINCIPLE	PITFALLS/LIMITATIONS	BENEFITS	ICU USAGE
A-mode	Received energy at a certain time displayed as amplitude	Obsolete	Obsolete	Obsolete
B-mode	Display of A-mode as brightness	Obsolete	Obsolete	Obsolete
M-mode	Display of B-mode over time	Difficult to interpret Angulation of cardiac chambers leads to inaccuracy	High temporal resolution	Wall thickness, TAPSE, MAPSE, premature closure of MV, SAM MV, early closure AV, FS/EF, RV diastolic collapse, volaemia
2D	Electronic/mechanical sweep of M-mode, reconstructed to provide real-time 2D images of anatomical structures	Temporal resolution less than M-mode Inaccurate positioning may lead to misinterpretation of chamber size	Images easily interpretable	Structural disease: chambers, valves, extracardiac structures
CW Doppler	Simultaneous transmission and receiving of US	Increasing incident angle leads to underestimation of velocities No spatial resolution along length of interrogation	Determines maximum velocity along length of interrogation	TR, PASP, pressure difference between any two chambers
PW Doppler	Emission of US and depth set by time to receive As change in velocity small, phase shift used	Incident angle dependent Limited velocity resolution	Determines velocity at specific point	LAP, CO, MPI, t-IVT
Colour Doppler	Based on PW Doppler principles Multiple sample volumes with blood flow velocity and direction colour coded Generally BART (blue away, red towards)	Need high-quality 2D images	Identification of normal/abnormal blood flow Facilitates alignment of CW Doppler	Valvular regurgitation, intracardiac shunts
TOE	Miniaturised US mounted on modified endoscope	Invasive	High resolution, easy imaging	Prosthetic valve endocarditis, intracardiac masses, inadequate TTE views Intraoperative imaging
R-sided contrast	US reflection of saline/blood interface Bubbles absorbed by pulmonary circulation	Adequate 2D imaging required	Safe, easy to perform and interpret	Intracardiac shunt (?differentiation from intrapulmonary)
TDI	As PW Doppler, but with filters set to detect low velocity	Incident angle dependent If poor image quality/low velocities difficult to interpret	Easier to measure than M-mode	Estimation LAP

Continued

Table 27.1 Principles and major pitfalls of echocardiographic techniques—cont'd

DEVELOPMENT	PRINCIPLE	PITFALLS/LIMITATIONS	BENEFITS	ICU USAGE
3D	Multiple PE crystals simultaneously transmitting and receiving	Need high-quality 2D images	Images that resemble real structures	Limited: mostly cardiology/cardiac surgery 3D EF if images adequate
Strain/strain rate	Deformation of adjacent parts of myocardial tissue based on TDI measurements for gradient of velocities	Incident angle dependent Translocation of tissue confound Load dependent	Identification of ventricular dysfunction not apparent by other means	Research tool, dyssynchrony Ventricular contractility
Speckle tracking	Tracking signature blocks of myocardial tissue	Need high-quality 2D images	Avoids incident angle Identification of all 4 vectors of LV movement	Research tool, dyssynchrony Ventricular contractility
HCU	Miniaturised device to facilitate usage	Quality of images, restriction of functionality	Small and portable	Cardiac arrest Basic echocardiography
Contrast	US reflective agents that pass through pulmonary circulation	Side effects, caution in low EF, high PAP	Improved endocardial border delineation Demonstration of coronary perfusion	EF Infarction i/c masses
ICE	Miniaturised US catheter	Cost	High resolution	Interventional cardiology
Disposable TOE	Miniaturised US probe	Cost, single plane, resolution, limited functionality	Size, duration of usage	Proposed as monitor

A-mode=amplitude mode, B-mode=brightness mode; M-mode=motion mode; TAPSE=tricuspid annular plane systolic excursion; MAPSE=mitral annular plane systolic excursion; MV=mitral valve; SAM=systolic anterior motion; AV=aortic valve; FS=fractional shortening; EF=ejection fraction; RV=right ventricle; US=ultrasound; CW=continuous wave; TR=tricuspid regurgitation; PASP=pulmonary artery systolic pressure; PW=pulse wave; LAP=left atrial pressure; CO=cardiac output; MP=myocardial performance index; t-IVT=total isovolumic time; TTE=transthoracic echocardiography; PE=piezoelectric; TDI=tissue Doppler imaging; HCU=hand-carried ultrasound; ICE=intracardiac echocardiography; i/c=intracardiac; TOE=transoesophageal echocardiography.

intensivist/anaesthetist should manage the airway, ensure haemodynamic stability, and where required modify the haemodynamics according to those required by the operator.

Challenges in ICU echocardiography relate not only to difficulties in image acquisition; but also the confounding effects of sedation, positive-pressure ventilation, pharmacological/mechanical circulatory support, loading conditions, and changes in the metabolic milieu.[4] The critical care echocardiographer must consider all these factors before accurate interpretation is possible, and remember that normal values for indices commonly measured in the non-critical care setting may not be applicable to the ICU population.

INDICATIONS FOR ICU ECHOCARDIOGRAPHY

Although the commonest reason to request an ICU echocardiogram is to assess LV function, indications for ICU echocardiography should rather be to answer a specific clinical question; monitoring effects of therapeutic interventions, formulating a diagnosis and/or suggesting interventions whereby cardiac output (CO) can be improved. The potential scope for ICU echocardiography outlined in the literature is summarised in **Table 27.2**. The most important role is first to rule out/diagnose potentially treatable cardiac disease, either leading to ICU admission, or contributing to the patient's clinical status. When significant cardiac pathology has been excluded, echocardiography should then be used to evaluate the patient's haemodynamics and monitor the effects of interventions.

DIAGNOSTIC ECHOCARDIOGRAPHY

Cardiac pathology may either be the primary reason for ICU admission, in which case it is likely to be severe, or otherwise an incidental finding, contributing to morbidity. Echocardiography should diagnose/exclude significant ventricular disease (including myocardial ischaemia/infarction or complications thereof),

Table 27.2 Indications for echocardiography in the critically ill

EMERGENCY AND ACUTE MEDICINE/ICM	INTENSIVE CARE MEDICINE
• Penetrating trauma, blunt trauma • Postcardiotomy due to cardiac surgery • Hypotension, shock of unknown origin • Unconsciousness, unresponsiveness • Acute severe dyspnoea • Syncope in young adults • Vein thrombosis • AMI and its mechanical complications • Atypical chest pain: suspected aortic dissection, suspected aortic abdominal/thoracic aneurysm, non-traumatic cardiac rupture • Iatrogenic complications from invasive procedures (e.g. pacemaker insertion, PCI, EP) • Great vessel disease	• Systolic function and RWMA abnormalities • Diastolic function • Hypovolaemia and volume responsiveness • Tamponade and pericardial disease • The sepsis syndromes • Preload, afterload and filling status • Acute cor pulmonale • Hypoxaemia • Complications of AMI • Chest trauma • Assessment of shock • Failure to wean from mechanical ventilation • Haemodynamic measurements • Position of cannulae for extracorporeal support
CARDIAC ARREST	
• Underlying rhythm: pulseless electrical activity/EMD/VF • Underlying cause: hypovolaemia/tension pneumothorax/tamponade/coronary thrombosis/pulmonary embolism • Guidance of intervention: volaemia/drainage of tamponade • Early detection of ROSC • Bradycardia–asystole, pacemaker–ECG • Performance of CPR • Effectiveness of chest compressions • Post-arrest hypotension/low CO state: adaptation of vasopressors/inotropes/volaemia	

RWMA=regional wall motion abnormalities; AMI=acute myocardial infarction; EP=electrophysiological; PCI=percutaneous cardiac intervention; EMD=electromechanical dissociation; VF=ventricular fibrillation; ROSC=return of spontaneous circulation; ECG=electrocardiogram; CPR=cardiopulmonary resuscitation; CO=cardiac output.

valvular disease, non-valvular obstruction to flow (LV outflow tract obstruction, pulmonary embolism) and/or pericardial pathology[4] (**Table 27.3**).

VENTRICULAR FUNCTION

Although commonly performed, standard measurements of ventricular function are rarely helpful beyond the initial diagnostic study as values may change significantly with volume loading, ventilation, inodilator therapy and other ICU interventions. Further, the RV is often neglected, and normal values for ventricular function (right and left) in the ICU are poorly defined.

LEFT VENTRICLE

LV contractility is complex, with systolic function comprising minor and long-axis contraction, rotational and differential basal and apical rotational vectors, and diastolic function an equally complex, active process.[3] A number of techniques exist to assess LV function, including measurement of dimensions and volumes in two/three dimensions, wall thickness and motion, assessment of filling patterns and measurement of myocardial deformation. None assesses all components of contractility, and all are variably load and inotropy dependent; therefore measured values should be interpreted with caution in the critically ill.

LV systolic function

Traditionally, assessment of LV contractility has depended upon linear measurement of changes in LV internal dimensions (fractional shortening, FS) or differences between systolic and diastolic areas/volumes in the minor axis (ejection fraction, EF), rather than thickening of the myocardium per se. Nevertheless, in cardiology, values have been correlated with prognosis in numerous pathological processes. Experienced echocardiographers can visually estimate EF by eyeballing alone; however, of note, normal values of FS/EF are unknown for the critically ill patient population, and remain highly variable depending upon ICU interventions as well as the inherent contractility of the myocardium. Although three-dimensional (3D) assessment of EF may be superior to 2D measurements, they are equally load dependent.[6]

In addition to global function there may be regional functional abnormalities, which may manifest as myocardial thinning (normal 6–12 mm), and/or abnormal motion (hypokinesis/akinesis/dyskinesis). In order to assess the myocardium comprehensively it is divided into 17 segments, each of which is individually evaluated, and any wall motion abnormalities correlated with the relevant coronary artery territories.[3] Positive inotropic agents may induce ischaemia (hence their use for stress echocardiography) with consequent

Table 27.3 Clinical and echocardiographic findings on the ICU

CLINICAL FINDING	CARDIAC CAUSE	ECHOCARDIOGRAPHIC FINDING	NOTES
Low CO unresponsive to inotropes	Valvular disease	Any severe stenotic or regurgitant lesion	Difficult to assess in ICU Sequential stenotic lesions may mask severity of individual lesions
	Intrinsic cardiac disease	HOCM/LVH with LVOTO Large VSD/ASD Severe LV/RV dysfunction	See text
	Extrinsic cardiac disease	Tamponade, pericardial effusion, pericardial disease	NB Postoperative cardiac surgical patients (see text)
Oliguria	Underfilling	Low transmitral/tricuspid velocities Small ventricular volumes Apposition of LV papillary muscles in systole	If severe LVH papillary apposition may be unreliable sign
	Intrinsic cardiac disease	Poor LV function, severe AS	High LAP demonstrated
	Pericardial disease	Pericardial effusion, pericardial tamponade, pericardial constriction	NB Postoperative cardiac surgical patients (see text)
Increased filling pressures (left-sided)	Impaired LV	Increased E > A ratio (corrected for age), short IVRT	See text for detailed explanation
	MV disease	Significant MS or MR	MR: dynamic ventricle, increased forward velocities (>1 m/s), short-duration and low-velocity (<3 m/s) regurgitant jet
Increased filling pressures (right-sided)	Secondary to left-sided disease	Significant AS, AR, MS, MR/LV disease	
	Impaired RV	Reduced TAPSE	Any reduction in association with PHT is significant Mild impairment after CABG is normal
	TR	Annular dilatation or endocarditis	If severe, RV dynamic with increased forward velocities (>1 m/s), short-duration and low-velocity regurgitant jet
Sepsis/SIRS	LV/RV dysfunction	Ventricular dilatation, systolic/diastolic dysfunction	Changes controversial and may be masked by inotropes
	Source of sepsis	Endocarditis	
Endocarditis	Native/prosthetic valve, pacemaker wires, extracardiac 'endocarditis'	Vegetations, paraprosthetic leaks, aortic root abscess	Vegetations rare in prosthetic valve endocarditis
Pulmonary hypertension	Acute PE	Dilated RV, severe TR	May rarely demonstrate intracardiac thrombus
	Post-pneumonectomy	Displaced heart, increased pulmonary acceleration time	Views often difficult even with TOE
	Mitral valve disease	Significant MS or MR (2D, PW, CW and colour Doppler)	Severe MR in ICU may be difficult to diagnose (see text)
Failure to wean from ventilator	Intrinsic cardiac disease	Ischaemia, severe MR, HOCM, LV/RV dysfunction	Stress echo may be necessary to make diagnosis
CVA/embolic event	Intracardiac thrombus	LA appendage, RA, apical LV thrombus Endocarditis	Exclude intracardiac shunt with contrast study
Cyanosis	Intracardiac shunting	Positive contrast study	Use agitated blood/saline. Perform Valsalva manoeuvre

induction of abnormalities in myocardial motion. Thus any ICU echocardiogram should be interpreted in the context of the level of inotropic support, and where abnormalities in contractility conform to known coronary artery territories, ischaemia/infarction should be suspected.

Although the majority of LV myocardial fibres are arranged circumferentially, longitudinal fibres situated in the subepicardium and subendocardium play a major role in maintaining normal function, accounting for long-axis (LAX) movement of the base with respect to the apex of the heart. LAX function has three components: amplitude, velocity and timing, and is measured using M-mode (mitral annular plane systolic excursion, MAPSE) and velocities of this motion assessed using tissue Doppler imaging (TDI).[7,8] As these fibres are subendocardial, they are exquisitely sensitive to ischaemia. Regional abnormalities in MAPSE correlate with infarction demonstrated on myocardial perfusion imaging, and may occur in the presence of dobutamine before the appearance of standard regional wall motion abnormalities and/or ECG changes.[9]

LV diastolic function[3,10]

In the normal heart, LV filling is biphasic, with early passive flow (E-wave) and late flow from atrial contraction (A-wave). Derived measures of diastolic function include isovolumic relaxation time (IVRT, time from aortic valve closure to mitral valve opening, normal 70–110 ms), ratio of peak velocities (E/A, normal 0.75–1.40), and E-wave deceleration time (normal 160–240 ms; **Fig. 27.1a**). Where diastolic dysfunction occurs (in either ageing and/or ventricular disease) there may be progressive prolongation of the IVRT (>110 ms) resulting in a lower early-diastolic pressure difference between LA and LV, an E-wave consequently

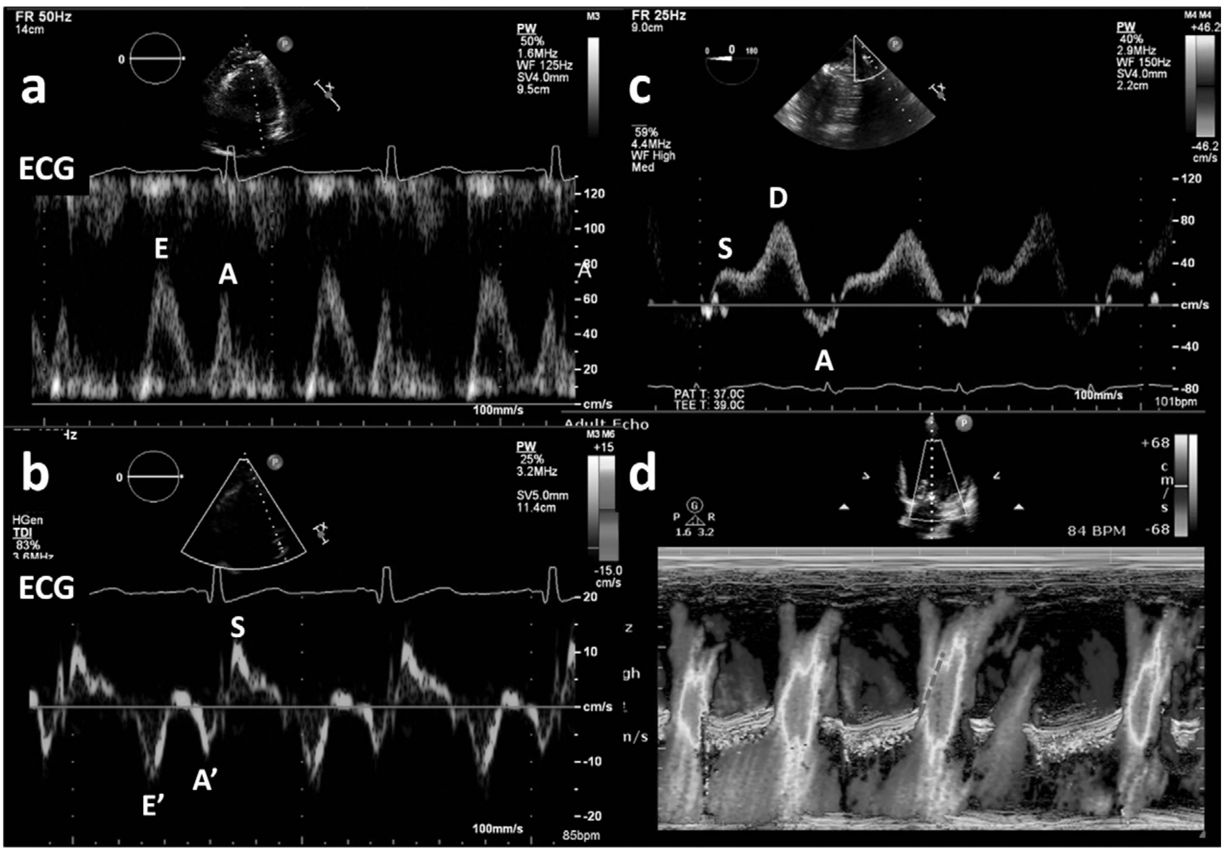

Figure 27.1 Methods for estimation of left atrial pressure using different types of Doppler. (a) PW Doppler across mitral valve showing dominant E wave, normal E deceleration time in a young patient with normal ejection fraction. (b) Tissue Doppler imaging of the lateral wall of the left ventricle, with systolic (S), E′ and A′ waves from the same patient as shown in (a). E/E′ is <10, indicating the left atrial pressure is not elevated. (c) PW Doppler of the pulmonary veins (TOE) with systolic (S), diastolic (D) and atrial (A) components in a patient with elevated left atrial pressure (suppression of the early S wave, with dominant D wave). (d) colour Doppler showing an M-mode of the inflow of the mitral valve, with the fastest aliasing velocity (red line). For explanation, see text. PW=pulse wave; TOE=trans-oesophageal echocardiography; ECG=electrocardiogram.

of lower velocity, a longer deceleration time (>240 ms) and an A-wave of progressively higher velocity. Thus, as normal values are age, inotropy, and filling dependent, as well as varying with pathology, interpretation in critically ill patients is challenging. Colour flow propagation velocity (CFPV; Fig. 27.1d), as determined by colour M-mode Doppler, has been proposed as a measurement to diagnose LV diastolic dysfunction (<50 cm/s indicating diastolic disease). Closely related to the time constant of isovolumic relaxation (Tau), CFPV is independent of heart rate, and relatively preload insensitive; however, TTE image quality on the ICU may limit its use. Finally, tissue Doppler imaging (TDI) of the myocardium at the base of the heart may assist in the diagnosis. Here early myocardial tissue velocities (E′) correlate with invasively measured Tau, thus providing a measure of myocardial relaxation (E′ of ≥10 cm/s is normal relaxation, <10 cm/s is impaired, and <5 cm/s is severely impaired; Fig. 27.1b,c).

RIGHT VENTRICLE

The RV is exquisitely sensitive to increases in afterload and reduction in coronary perfusion, and fails due to one or both of these factors, readily demonstrated using echocardiography.[11] In the ICU, RV dysfunction is commonly secondary to pulmonary disease/ventilation and/or LV dysfunction, where again echocardiography is pivotal for diagnosis. A range of techniques is used to assess RV function, including M-mode, PW Doppler and TDI.

RV systolic function

Due to its complex geometry, assessment of RV volumes using 2D echocardiography is challenging, with poor reproducibility. Normal RV wall thickness is 3.3 + 0.6 mm, and is smaller than the LV (RVEDA/LVED< 0.6).[3] Measurement of the longitudinal annular movement of the RV free wall using M-mode (tricuspid annular plane systolic excursion, TAPSE) correlates well with radionuclide and cardiac magnetic resonance assessment of RV function.[12] Normal TAPSE is 2 cm (**Fig. 27.2d**), falling after cardiac surgery to 1.5 cm,[12] and any reduction in TAPSE in the setting of pulmonary hypertension indicates significant RV dysfunction; an amplitude of <1 cm implies severe impairment. 3D echocardiography for assessment of RV function has a potential role, as although reportedly systematically underestimating RV volumes it is demonstrably superior to 2D for assessing contractility.[13]

RV diastolic function

The principles of assessment of LV diastolic function theoretically apply equally to the RV, although the isovolumic phases of the cardiac cycle are shorter, and more ill defined, transtricuspid velocities are lower, and subject to significant respiratory variation. RV restriction is common (43–50% ICU patients) and diagnosed by demonstrating forward flow across the pulmonary valve in late diastole (**Fig. 27.3a**).[14] Positive-pressure ventilation may abolish this pulmonary arterial diastolic wave, making the diagnosis more challenging. Further confounding factors include the presence of LV restriction, elevation of pulmonary arterial diastolic pressures, tachycardia and requirement for high ventilatory pressures.

GLOBAL MEASURES

A number of measures of systolic and diastolic (global) ventricular function have been proposed, the myocardial performance (Tei) index and total isovolumic time (t-IVT). The Tei index combines systolic and diastolic Doppler assessment, is simple to calculate, reproducible, independent of heart rate, blood pressure and characterised by low interobserver and intraobserver variability, and can be calculated for both the right and left heart (Tei=IVCT+IVRT/ET, normal LV=0.37±0.05, normal RV=0.28±0.04).[3,15] Although predictive of mortality and morbidity in numerous cardiac pathologies, it is load and activation dependent, and is not well validated in the ICU. t-IVT is a marker of global ventricular electromechanical dyssynchrony, and effectively wasted time during the cardiac cycle (t-IVT=60-total filling time-total ejection time, normal <14 s/min).[3,16] Although also not well validated in the ICU setting, an abnormally prolonged t-IVT should prompt a search for the underlying cause (ischaemia/ventricular dyssynchrony) and provide guidance for interventions to optimise CO. In selected patients, SV and CO can be increased by echocardiographically guided optimisation of pacing (36–43% increase), identified by demonstration of a prolonged t-IVT (up to 23% cardiothoracic patients).[17]

VALVULAR FUNCTION[3,18–19]

Valvular heart disease as a primary cause of ICU admission is likely to be severe, and affecting the left-sided valves. Pulmonary and tricuspid valvular disease rarely causes acute illness mandating ICU admission, unless associated with endocarditis.. The epidemiology and clinical manifestations of valvular heart disease relevant to intensive care are described in Chapter 25.

AORTIC STENOSIS

The echocardiographic diagnosis of aortic stenosis (AS) depends upon a number of features, including the presence of immobile valve leaflets, and demonstration of a significant increase in blood velocity as it crosses the narrowed valve orifice (high gradient). Echocardiographic features of severe AS are shown in **Table 27.4**.[18] Where LV function is poor and CO low, the increase in velocities across the aortic valve may be correspondingly low, and significant AS missed. Although there are no agreed values for what constitutes significant AS in the critically ill patient, a ×4 step-up in velocity across the valve probably indicates severe AS. TOE is

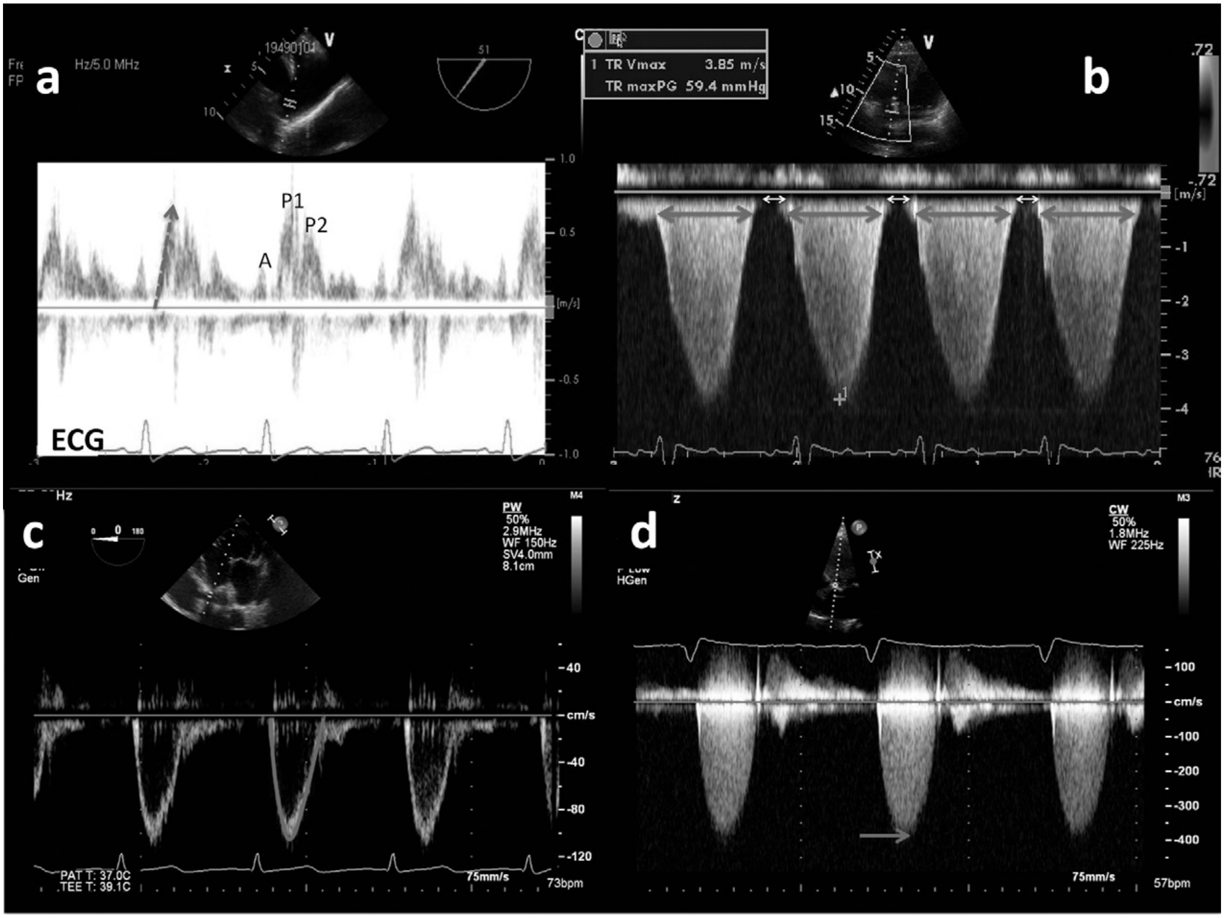

Figure 27.2 Echocardiographic features of pericardial collections (a) TTE parasternal long axis view in a patient with pleural and pericardial collections. The anatomical limits of the pericardial collection (P) are demonstrated with it appearing anterior to the descending aorta (*). The pleural collection (PL) can extend posterior to the descending aorta. The parietal pericardium (arrowed) is clearly seen between the two. Intra-cardiac shunting on echocardiography. (b) TTE subcostal view evidence of diastolic collapse on M-mode subcostal view. (c) 2D TOE showing a secundum ASD in a hypoxic patient with peumonia referred for extracorporeal membrane oxygenation. The left atrium is at the to of the image and shunting across the defect is clearly seen on colour Doppler (arrowed). Contrast TTE (apical 4-chamber view) in a patient with a large PFO. Here, the right heart is fully opacified with bubbles, and the LV partially opacified. (d) Evaluation of the RV systolic function: movement of the annulus with respect to the apex is measured using M-mode taken from the apical 4 chamber view (TTE), and demonstrated over time for (a) right ventricle, TAPSE. LV=left ventricle; P=pericardial collection; PL=pleural collection; RA=right atrium; RV=right ventricle; LA=left atrium; LV=left ventricle.

generally not indicated to confirm the diagnosis (Fig. 27.3d); however, an expert opinion should be sought regarding the TTE findings, as stress echocardiography may be indicated. Relevant additional echocardiographic findings include the degree of LV hypertrophy and dysfunction, pulmonary hypertension and the presence of concomitant valve disease (in particular in the presence of rheumatic AS or endocarditis).

AORTIC REGURGITATION

Aortic regurgitation (AR) is diagnosed using echocardiography by demonstration of a volume-loaded, dilated LV, and regurgitant jet using colour Doppler, confirmed using CW Doppler, together with inspection of the valve leaflets/aortic root. The diagnosis should be suspected in a patient with a low CO state associated with a hyperdynamic LV. Severe AR results in high forward velocities across the aortic valve, diastolic regurgitant velocities falling to <2 m/s at end-diastole, and holodiastolic flow reversal in the descending aorta. Echocardiographic features of severe AR are shown in Table 27.4.[18] Where AR is catastrophic, aortic velocities may reach zero before end-diastole, followed by diastolic MR. Here, M-mode of the mitral valve demonstrates premature closure.

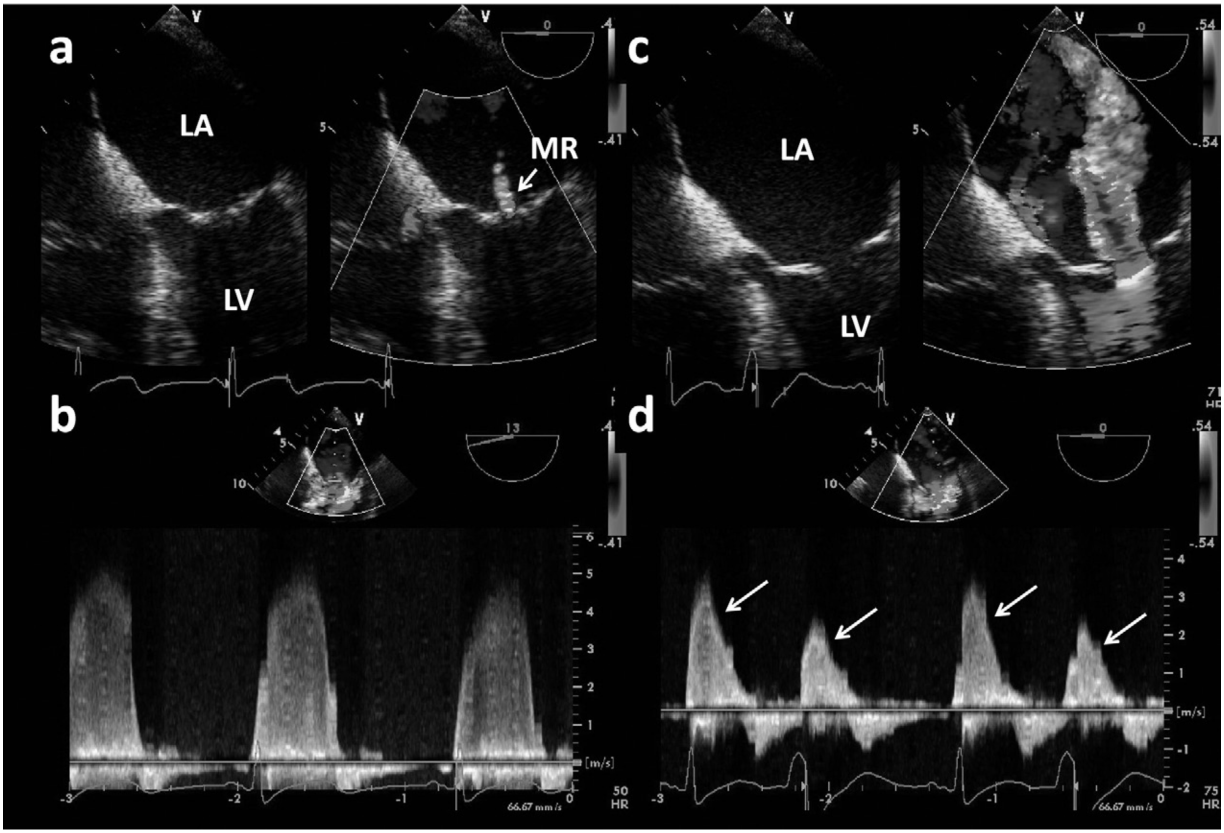

Figure 27.3 Doppler echocardiographic features of pulmonary hypertension and high pulmonary vascular resistance. (a) TOE showing PW Doppler across the pulmonary artery in a patient with severe pulmonary hypertension. The pulmonary acceleration time (time from onset to peak of forward flow, dotted arrow) is short, indicative of a high pulmonary vascular resistance. The presence of a double component of the pulmonary systolic wave (P1 and P2) is expression of high pressure. The pre-systolic pulmonary arterial wave (A) is indicative of RV restrictive physiology, corresponding to forward flow in late diastole as a result of atrial contraction (p wave on the ECG). (b) CW Doppler across the tricuspid valve in pulmonary hypertension showing TR. The peak systolic velocity between RV and RA is 3.9 m/s, corresponding to a peak gradient of 59.4 mmHg. Right atrial pressure was 20 mmHg, therefore calculated PASP is 59.4+20=19.4 mmHg. In addition, the TR is long (540 ms, solid red arrows), due to prolonged RV activation, and therefore limiting the time available in diastole for RV filling (white arrows). See text for full explanation. For orientation a miniaturised 2D figure is shown at the top of each image. ECG=electrocardiogram; TOE=transoesophageal echo; PW=pulse wave; RV=right ventricle; CW=continuous wave; TR=tricuspid regurgitation. Doppler evaluation of flow from the left heart. (c) PW Doppler with sample volume positioned in the left ventricle outflow tract, just below the aortic valve (shown by the parallel lines in the miniature 2D image at the top of the figure). The flow is laminar and moving from the LV to the descending aorta, away from the probe (flow is negative to respect to the baseline on Doppler trace). Tracing the envelope (shown in red) gives the velocity-time integral which when multiplied by the LVOT area gives the stroke volume. (d) CW Doppler across the LVOT and aortic valve in a patient with aortic stenosis (sample line dotted in miniature 2D image at the top of the figure). Peak velocity (arrowed in red) is 4 m/s, corresponding to a peak velocity of 64 mmHg (for explanation see text). ECG=electrocardiogram; PW=pulse wave; 2D=two dimension; LV=left ventricle; LVOT=left ventricular outflow tract; CW=continuous wave.

Care should be taken in the presence of significant LV disease, as equalisation of aortic and LV pressures at end-diastole measured by Doppler may occur owing to either very low aortic pressures (severe AR) or very high LV end-diastolic pressures (severe LV disease). Furthermore, the two entities may coexist. Where severe AR is diagnosed, echocardiography should be used to demonstrate the underlying cause and its complications, including endocarditis (vegetations/root abscess/abnormal communications/involvement of other valves) and dissection (anatomy of the dissection/coronary artery involvement/pericardial collection). In patients with suspected dissection, undertaking TOE should be integrated with surgical decision making/

Table 27.4 Echocardiographic parameters in severe valvular disease

	SEVERE STENOSIS	
	AORTIC STENOSIS	MITRAL STENOSIS
Valve area (cm^2)	<1.0	<1.0
Indexed valve area (cm^2/m^2 BSA)	<0.6	—
Mean gradient (mmHg) (kPa)	>40 (>5.32)	>10 (>1.33)
Maximum jet velocity (m/s)	>4.0	—
Velocity ratio	<0.25	—
	SEVERE REGURGITATION	
	AORTIC REGURGITATION	*MITRAL REGURGITATION*
Valve morphology	Abnormal/flail/large coaptation defect	Flail leaflet/ruptured papillary muscle/large coaptation defect
Colour flow regurgitant jet	Large in central jets, variable in eccentric jets	Very large central jet or eccentric jet adhering, swirling and reaching the posterior wall of the left atrium
CW signal of regurgitant jet	Dense	Dense, triangular
Other	Holodiastolic flow reversal in descending aorta (EDV >20 cm/s)	Large flow convergence zone

BSA=body surface area; CW=continuous wave; EDV=end-diastolic velocity.

timing, as the risk of catastrophic haemodynamic destabilisation/progression of the dissection is significant. Depending upon local protocols, another imaging modality may be used to confirm the diagnosis, and TOE limited to intraoperative use.

MITRAL REGURGITATION

Quantification of mitral regurgitation (MR) is challenging, and confounded by the effects of positive-pressure ventilation and the use of vasoactive agents, as these may significantly alter the degree of regurgitation. Severe MR is diagnosed by demonstration of a dynamic, volume-overloaded LV in the presence of a low CO state plus a characteristic regurgitant jet on CW Doppler that is short, with a low velocity (<3 m/s) and high forward transmitral velocities (>160 cm/s). Echocardiographic features of severe MR are shown in Table 27.4.[18] In catastrophic MR, regurgitant flow may not be well visualised with colour Doppler, and PW Doppler across the valve may show low-velocity, sinusoidal, laminar flow. In assessing MV disease, the whole valve apparatus should be evaluated (leaflets, annulus and LV) and leaflets systematically analysed according to the Carpentier classification.[3,18,19] Care should be taken when assessing the MV following a penetrating chest wound, as a longitudinal injury to the anterior leaflet may result in its appearing structurally normal, despite having a significant defect. Secondary (functional) MR may be dynamic, and if suspected stress echocardiography should be considered. Where severe MR of any aetiology is suspected in a critically ill patient, expert TOE should be performed (**Fig. 27.4**).

In a small group of patients with left bundle branch block (LBBB), ventricular filling is temporally limited by the duration of MR, which may be only mild in terms of regurgitant volume. Here any increase in heart rate may result in further shortening of ventricular filling time, thereby limiting SV and CO.[20] In the outpatient setting, optimally timed AV delay pacing (using echocardiography) may increase SV significantly, although this has not yet been systematically demonstrated in the ICU setting.

MITRAL STENOSIS

The echocardiographic diagnosis of mitral stenosis (MS) depends upon demonstration of a structural abnormality of the leaflets (and/or subvalvular apparatus), together with an increase in blood velocity across the valve measured using Doppler. Thus, the diagnosis of MS may be challenging when the CO is low and echocardiographic transvalvular velocities are correspondingly low. Echocardiographic features of severe MS are shown in Table 27.4.[18] Additional findings that support the diagnosis include significant LA dilatation, pulmonary hypertension, RV dysfunction, and rheumatic involvement of other valves. Where diagnosed, expert TOE examination should be performed to determine the structural abnormalities of the valve and potential suitability for balloon mitral valvuloplasty, including presence/absence of left atrial thrombus.

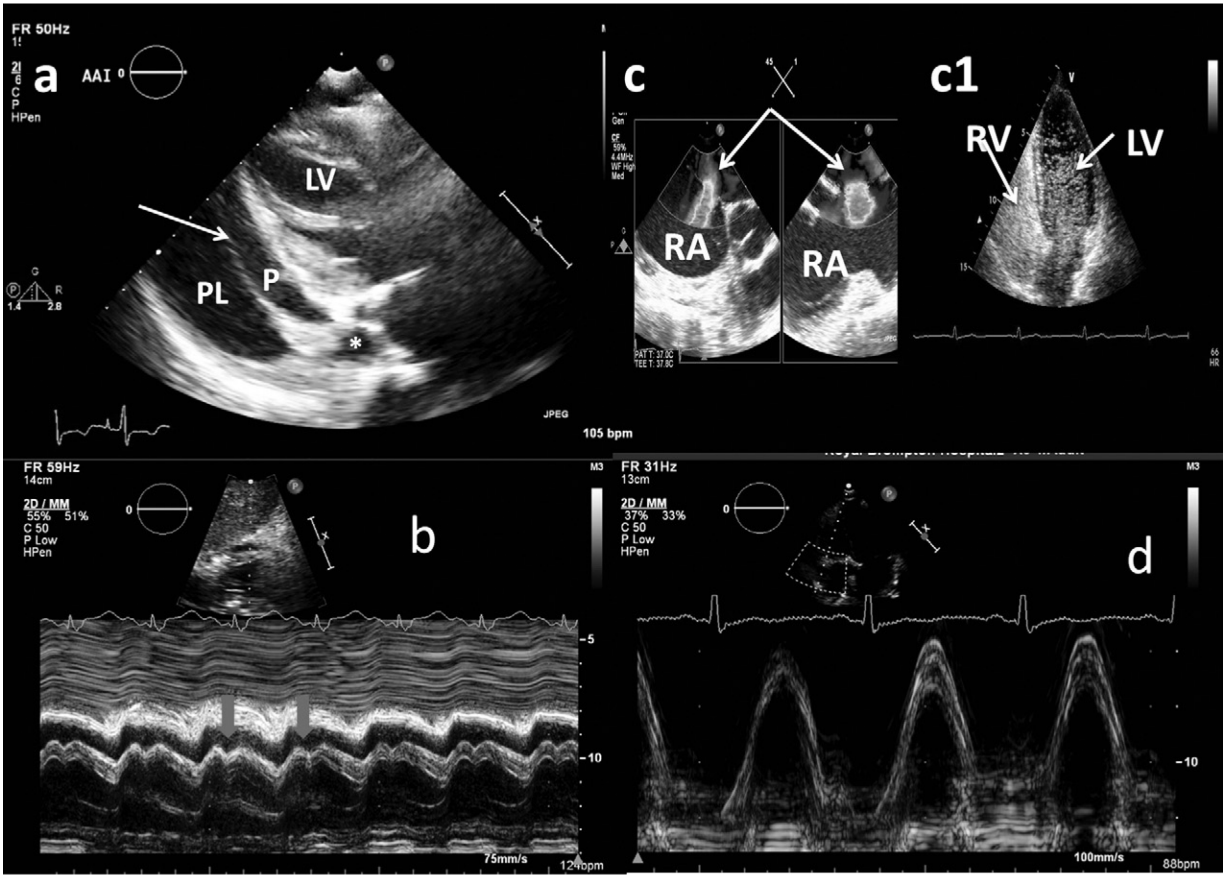

Figure 27.4 Echocardiographic features of dynamic MR under rest conditions (a & b) and after pressor and volume loading (c & d). (a) TOE mid-oesophageal 4-chamber view, focusing on the MV in systole. A small jet of MR is seen between the two central leaflets of the MV. (b) The corresponding CW regurgitant Doppler trace with a high velocity (5 m/s) and dome-like appearance. (c) after volume and pressor loading the MV leaflets no longer coapt (seen on the 2D image, left) and there is a corresponding broad jet of MR which is laminar and reaches the back of the LA. (d) CW Doppler of MR from (c) is shown, with a fall in MR velocities (despite increase in systemic pressures) and change in shape to triangular demonstrating the V-wave cutoff sign (arrowed). LA=left atrium; LV=left ventricle; MR=mitral regurgitation; TOE=transoesophageal echocardiography; MV=mitral valve; 2D=two dimensional.

PROSTHETIC VALVE MALFUNCTION

Significant prosthetic valve malfunction may result from either obstruction (pannus/thrombus) or regurgitation (paravalvular/valvular), which may be due to leaflet degeneration (biological prostheses) or endocarditis. Echocardiographic features include demonstration of a volume-overloaded LV, and/or evidence of normalisation of septal motion on TTE, together with direct evidence of valve malfunction (stenosis/regurgitation). Suspected infection of a prosthesis is an indication for expert TOE. In contrast to native valve endocarditis, it is unusual to see vegetations on a mechanical valve as infection tends to destroy the suture line rather than lead to the development of large masses.[3,18] The ability of echocardiography to differentiate between endocarditis and valve leaflet degeneration in bioprosthetic valvular regurgitation is limited, particularly where there is significant leaflet calcification; however, the presence of paraprosthetic regurgitation/abscesses supports the diagnosis of infection. Similarly, echocardiography is not the imaging modality of choice when differentiating between pannus and thrombus; here CT has been shown to be superior.

PERICARDIAL DISEASE

The pericardium comprises two layers, containing approximately 50 mL pericardial fluid (normal intrapericardial pressure −2 to 2 mmHg (−0.266 to 0.266 kPa)). Intrapericardial pressure falls with intrapleural pressure during inspiration (spontaneous ventilation) with a fall in right-sided cardiac pressures, and corresponding increase in right heart velocities. These

effects are frequently exaggerated in patients with clinically significant pericardial disease, the most common of which is tamponade. Although primarily a clinical diagnosis, echocardiography can be used to confirm the diagnosis and to guide pericardiocentesis.

TAMPONADE

Tamponade is variably defined, but is an impairment of cardiac filling due to a rise in intrapericardial pressure, irrespective of the volume of pericardial collection. Hence, a small, rapidly accumulating collection may have profound haemodynamic effects, and by contrast a slowly accumulating, large collection may be associated with a modest rise in intrapericardial pressure and no haemodynamic effects. The first stage in echocardiographic diagnosis of tamponade is to demonstrate a collection within the pericardial space (Fig. 27.2a). This should be described according to its size, site and consistency. The second stage is to demonstrate the haemodynamic effects of the collection (Fig. 27.2b).[3] These all depend upon the pressure effects upon the relevant cardiac chamber, and may be modified in the presence of cardiac disease.

When the pericardial pressure exceeds that of a cardiac chamber, echocardiography may show chamber collapse; those with the lowest pressure are most vulnerable. Additionally, as pressures differ during the cardiac cycle, the vulnerability of each depends upon the phase of the cardiac cycle. Hence sequential demonstration of RV early-diastolic collapse, RA late-diastolic collapse, LA late-diastolic collapse and LV early-diastolic collapse may be seen as tamponade progresses. The sensitivity and specificity of these signs are variable, with RV diastolic collapse specific (85–100%) but less sensitive (60–90%) than sustained (>30% cycle) diastolic collapse of the RA. Additional features that support the diagnosis include a swinging heart, pseudosystolic anterior motion of the MV, and demonstration of fixed, dilated caval veins.

With the heart encased within a non-expansile collection, the normal respiratory variation in transvalvular flows will be exaggerated, demonstrated readily using echocardiography. Thus, in spontaneous ventilation, during inspiration as intrathoracic pressure falls, this results in an increase in venous return to the right heart, and this results in a shift of the interventricular septum, and a fall in left-sided flows. This exaggerated variation (>25% tricuspid or >15% mitral) is regarded as abnormal, and corresponds to the clinical sign of pulsus paradoxus. Positive-pressure ventilation reverses the effect.

HAEMODYNAMICS

In addition to its role in diagnosis of underlying cardiac disease, echocardiography can be used as an adjunct for assessment of haemodynamics. It is important to note that echocardiography cannot measure pressures per se, but rather the velocity of blood moving from one chamber to another as a result of a pressure difference between the two chambers. Any pressure measurements are therefore derived, and should be interpreted with care.

CARDIAC OUTPUT AND STROKE VOLUME

Stroke volume (SV) is measured using echocardiography by multiplying the velocity–time integral (VTI, also known as stroke distance, normal 20 cm) by the cross-sectional area of the relevant outflow tract at that point (LV or RV). VTI is measured using PW Doppler (Fig. 27.3c) immediately (5–10 mm) proximal to either the aortic or pulmonary valve, and the relevant outflow tract dimension measured at the same point. The greatest source of error is calculation of the cross-sectional area as images may be suboptimal, the outflow tract non-circular, and any error in radial measurement will be magnified (area $=\pi r^2$). As outflow tract dimensions measured do not vary over the short term, trends in VTI may be used to monitor changes in SV.

LEFT ATRIAL PRESSURES

A number of echocardiographic techniques either alone or in combination can be used to estimate left atrial pressure (LAP). These range from the use of traditional techniques (M-mode and phonocardiography) to more complex and modern applications (TDI).

As LAP rises, the pattern of transmitral flow changes. Thus, where there is severe reduction in ventricular (or pericardial) compliance the increase in filling pressure causes abnormalities in LV filling. Here, as LAP increases, equalisation of atrial and ventricular pressures occurs early, the mitral valve opens earlier than normal (short IVRT is <60 ms), the increased LAP increases the transmitral gradient in early-diastole (increasing E-wave peak) with rapid equalisation of ventricular and atrial pressures (short E deceleration time <160 ms).[3,10] Further, because of the high LVEDP, little/no filling occurs with atrial contraction and the A-wave is markedly reduced or absent – restrictive physiology. However, because of the conflicting effects of ageing and pathology, none of these parameters can be used alone to estimate LAP.

Combining transmitral Doppler (blood velocities) with TDI (tissue velocities) has been shown to improve the correlation with LAP. Here, the ratio E/E′ is calculated, with a ratio <10 corresponding to LAP < 15 mmHg (2 kPa), and ratio >15 corresponding to LAP > 18 mmHg (2.4 kPa); however, a number of controversies exist, and as correlation between 11–14 is poor, additional parameters should be used, generally in combination.[3,21,22] Thus, using PW Doppler indices, mitral E/A < 1.4, pulmonary vein S/D > 0.65 and EF > 44% have been shown to predict PAOP < 18 mmHg (2.4 kPa), and/or

using TDI and colour Doppler, a lateral E/E'<8.0 or E/Vp<1.7 predicted a PAOP<18 mmHg (2.4 kPa) (sensitivity of 83% and 80%, and specificity of 88% and 100%) (Fig. 27.1).[23]

PULMONARY ARTERY PRESSURES

Pulmonary artery systolic pressure (PASP) can be estimated by measuring maximal tricuspid regurgitation (TR) velocity using CW Doppler, and applying the simplified Bernoulli equation to convert this number into a pressure (RV pressure=4×(peak TR velocity)^2). Estimated right atrial pressure (RAP) is then added to calculate PASP. Care is needed in severe RV dysfunction, as PASP may be significantly underestimated by this technique; further, PASP may fall owing to progressive RV failure. In the absence of TR, the pulmonary regurgitation (PR) trace can be interrogated to estimate PA diastolic pressure (4×(PR end-diastolic velocity)^2 + RAP) and mean PA pressure (4×(PR peak velocity)^2). Finally, increased PVR is suggested by a short pulmonary acceleration time (<80 ms) and is calculated using the ratio of peak TR velocity to the RVOT VTI (PVR=TR/VTI_{RVOT}×10 + 0.16).[3,21]

RIGHT ATRIAL PRESSURES

Where invasive measurement of RAP is not available, echocardiography may be used to estimate its value, by measurement of IVC size (<20 mm vs >20 mm), degree of IVC inspiratory collapse (<50% vs >50%) and hepatic vein dimension (normal vs dilated).[3] However, their validity in the ICU population is questionable.

VOLUME RESPONSIVENESS

Echocardiography allows assessment of the patient's volume status, complementary to invasive haemodynamic measurements.[3,4,21] Echocardiographic volume status assessment is based on static values (single-measure dimensions and flows) and dynamic indices (variation in flows and dimensions after dynamic manoeuvres).

STATIC PARAMETERS

Estimation of preload- and volume-responsiveness using static measurements is generally unreliable. However, the following parameters have been suggested to indicate severe hypovolaemia in the critically ill: first, a small, hyperkinetic LV (in the presence of a normal RV) with end-systolic cavity obliteration, secondly LV end-diastolic area <5.5 cm^2/m^2 BSA and thirdly a small IVC (<10 mm) with inspiratory collapse (spontaneously breathing patients), or a small IVC at end-expiration with variable respiratory change (mechanically ventilated patients). In this scenario, though, the correlation between IVC dimensions and RAP is poor. LAP does not correlate with volume responsiveness, but demonstration of abnormally high pressures with a restrictive filling pattern should signal caution in volume resuscitation.

DYNAMIC PARAMETERS

These include a number of measures (including effects of mechanical ventilation and passive leg raising on cardiac function/filling status) to predict a potential increase in SV in response to filling. Passive leg raising has been proposed to predict fluid responsiveness in spontaneously breathing patients; however, sensitivity and specificity are relatively low, and the number and nature of confounding factors (intra-abdominal pressure, hypovolaemia, arrhythmia) probably limit its usefulness in the ICU population.

Cyclical changes in intrathoracic pressure induced by mechanical ventilation result in corresponding cyclical changes in right and left heart filling, and hence in SV (if the patient is on the ascending part of the Frank–Starling curve). Thus, respiratory variations in VTI may be used as an index of fluid responsiveness (cut-off 18% variation VTI, 12% variation peak LVOT velocity; **Fig. 27.5**) and are comparable with the techniques of systolic pressure, SV and pulse pressure variation measured using other monitors.[3,4,21,24] In addition, respiratory variation in SVC and IVC dimensions have been proposed to predict fluid responsiveness. An IVC distensibility index (maximum–minimum/minimum) >18% (12% normalised to mean value) has been suggested to predict a significant increase in SV in response to fluid challenge. In contrast, a high SVC collapsibility index (maximum–minimum/maximum) >36% predicts a positive response to volume expansion (≥15% increase in SV) with sensitivity 90% and specificity 100%. A number of caveats exist when interpreting dynamic volume responsiveness: patients must be in sinus rhythm, fully mechanically ventilated, with no spontaneous breathing effort. Further, the effects of lung protective ventilatory strategies may lead to false-negative values, and false-positive results may be seen in patients with RV disease.

ECHOCARDIOGRAPHY IN SPECIFIC SCENARIOS

A number of clinical scenarios/questions may be raised in the critically ill that potentially require focused echocardiography, rather than a fully comprehensive study. The ICU echocardiographer must know the potential pitfalls and coexisting pathologies in order to make a relevant assessment.

MYOCARDIAL ISCHAEMIA/INFARCTION

Echocardiography is included in the universal definition of myocardial infarction (MI), and suspicion of a mechanical complication of MI is a class IA indication for echocardiography.[19] Generally the extent of infarction/ischaemia should be demonstrated and

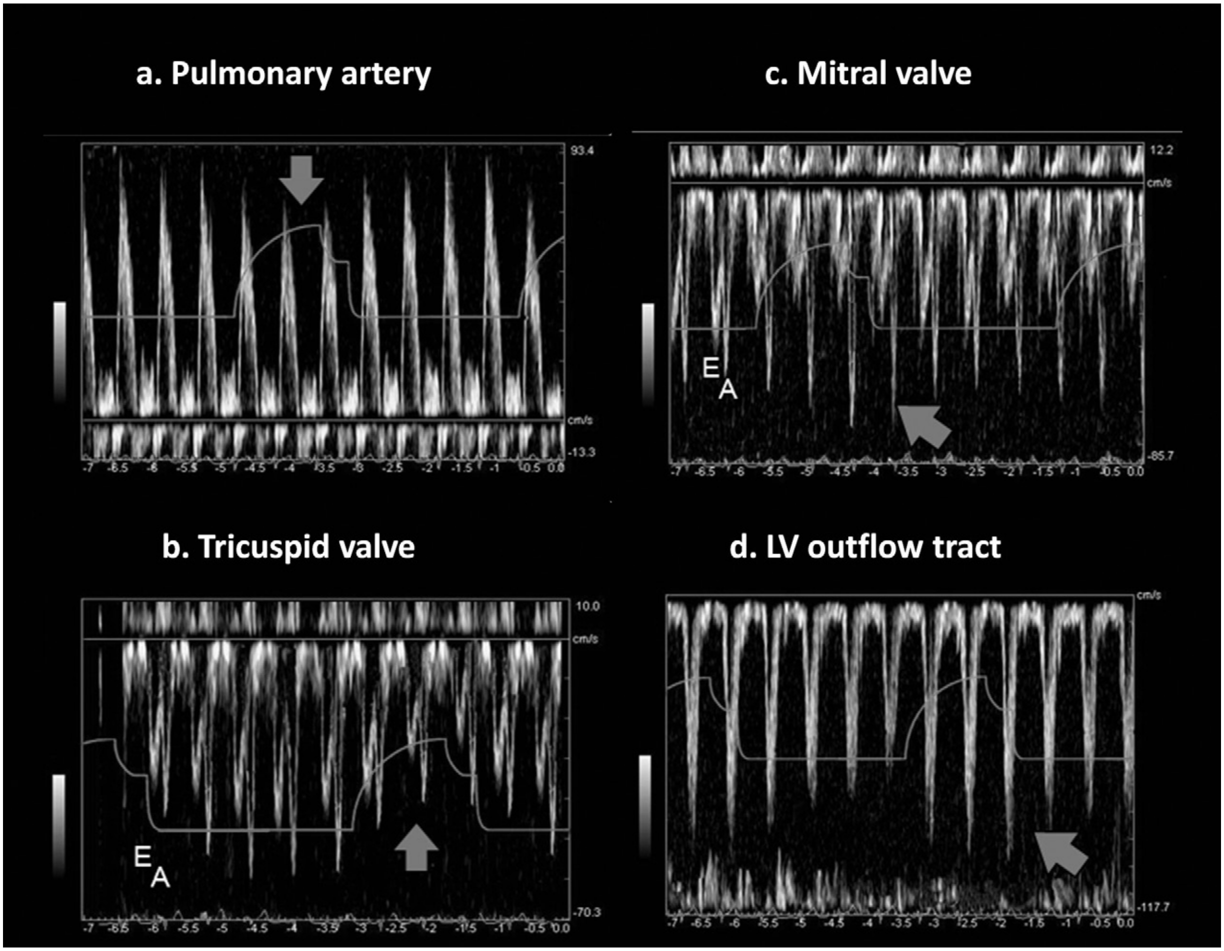

Figure 27.5 Variation in transvalvular flows in response to positive pressure ventilation measured using PW Doppler echocardiography, and superimposed ventilatory pressure waves shown in green. On the left of the figure, changes in right heart velocities are shown, and on the right, changes in left heart velocities. During inspiration there is a fall in peak velocity across the (a) pulmonary and (b) tricuspid valves. After inspiration there is a corresponding progressive fall in (c) transmitral and (d) LV outflow tract velocities (arrowed). For full explanation, see text. LV=left ventricle. Image courtesy of G. Via, Italy.

complications (MR, ventricular septal rupture (VSR)/cardiac rupture/RV infarction) actively excluded.

MR may result from complete/partial papillary muscle rupture, which is usually very severe. More common is posterior leaflet restriction due to inferior/posterior infarction/ischaemia, with associated functional MR, which may be dynamic, presenting as failure to wean from mechanical ventilatory support. Here a targeted echocardiogram performed when the patient is clinically compromised is indicated, and/or stress echocardiography (dobutamine+volume loading/pressor agents).

VSR is now a relatively uncommon complication, but should be suspected in patients post MI presenting with cardiogenic shock. Imaging may be challenging as rupture may occur at any point in the septum, the defects may be multiple, but are generally easily appreciated using colour Doppler. Care should be taken in interpreting LV function, as it may appear deceptively good (due to offloading to the RV), and additional assessment must include RV function, MR and PASP. A small amount of fluid in the pericardial space is common following transmural MI, rarely causing haemodynamic compromise. By contrast LV free wall rupture may occur, resulting in a very rapidly accumulating collection and catastrophic tamponade. RV infarction should be suspected in patients with occlusion of the proximal right coronary artery, and function assessed using standard parameters, together with measurement of PASP, LV function and exclusion of right–left shunting through a PFO. Differentiation between RV infarction and pulmonary embolism (PE) can be challenging, but suggested by the absence of pulmonary hypertension and coexistence of LV postero-inferior hypokinesia.

ACUTE COR PULMONALE (ACP)

This is characterised by a sudden severe increase in RV afterload resulting in acute RV dilatation and failure. Major causes of ACP include acute pulmonary embolism and ARDS.

PULMONARY EMBOLISM (PE)

The definitive diagnosis is made by demonstration of thrombi/masses in the pulmonary arteries, although in the majority of cases echocardiography provides only indirect signs of PE. These include pulmonary hypertension, signs of RV systolic overload (septal dyskinesia), diastolic overload, RV free wall hypokinesia and moderate–severe TR.[3,25] Pre-existing pulmonary hypertension is suggested by RV hypertrophy and PASP > 60 mmHg (7.98 kPa).

ACUTE RESPIRATORY DISTRESS SYNDROME

ACP occurs relatively commonly in this patient population, and has been shown to correlate with increased mortality. Where the diagnosis of ARDS/ALI is made, mechanical ventilation may have unfavourable effects on RV function, owing to altered pulmonary dynamics and secondary increase in alveolar pressure and PVR. Due to introduction of more lung-protective ventilatory strategies this is less frequently seen; however, a mild degree of RV dysfunction is common and, where present, ventilation can be altered to minimise plateau and positive end-expiratory pressures.[26] Diagnosis of RV dysfunction is important in patients with lung injury considered for mechanical circulatory support, as it may preclude the use of shunt-inducing devices (interventional lung assist/veno-venous extracorporeal membrane oxygenation).

HYPOXAEMIA

Echocardiography may be used in the diagnosis and management of hypoxaemic patients on the ICU, including establishing the differential diagnosis (cardiogenic vs non-cardiac), assessment of secondary effects of pulmonary pathology on cardiac performance, diagnosis of a low CO state and/or diagnosis of anatomical shunt (intracardiac or intrapulmonary).

Many ICU factors increase right-sided pressures, leading to right–left intracardiac shunting across an atrial septal defect/patent foramen ovale (Fig. 27.2c). Intrapulmonary shunts are independent of right-sided pressure, and have been described in ARDS, pneumonia, thoracic trauma and hepatic cirrhosis. The choice of technique to demonstrate shunting depends upon clinical context, quality of imaging and need for detection of intrapulmonary shunt; however, TOE is generally superior. Diagnosis depends on a positive agitated saline contrast study (intracardiac; microbubbles pass into the LA immediately vs intrapulmonary; delayed appearance microbubbles via pulmonary veins; (Fig. 27.2c)), visualisation of the relevant structural abnormality and colour Doppler confirmation. Provocative manoeuvres (i.e. Valsalva) may be required, and in the presence of high LAP a shunt may be missed.

WEANING FROM MECHANICAL VENTILATION

Discontinuation of positive-pressure ventilation increases LV afterload and preload, and significantly increases the rate–pressure product. In patients with cardiac disease this may result in the left and/or right heart being unable to match the increased work, leading to rising LAP, pulmonary oedema, and/or RV dysfunction. Echocardiography can diagnose a cardiovascular contribution to weaning failure, and suggest interventions to facilitate successful withdrawal of mechanical ventilatory support. A baseline echocardiogram should be performed at the start of the weaning trial, and evidence of inotropy, lusitropy, chronotropy (negative/positive), preload and afterload mismatch should be actively sought. Additionally evidence of increasing LAP, myocardial ischaemia, decrease in LV/RV global function and/or worsening atrioventricular valvular regurgitation suggests a cardiac contribution to failure to wean.

SEPSIS SYNDROMES

Echocardiography plays a key role in the management of the septic ICU patient by guiding haemodynamic management and excluding cardiac causes for sepsis. Sepsis-related LV dysfunction is well recognised, with global and regional wall motion abnormalities described in up to 60% of patients.[27,28] RV dysfunction develops in up to 30% of patients, either in isolation or associated with LV dysfunction.[29] Ventricular dysfunction can be masked by vasodilatation and/or inadequate preload and should be reassessed after haemodynamic optimisation.[4,30] Emerging evidence in the paediatric literature suggests strain/strain rate imaging may detect significant abnormalities in ventricular function in septic shock that are not detectable by conventional echocardiography.[31]

Echocardiography may reveal a cardiac source of sepsis related to either native/prosthetic valve infection or indwelling catheters/implanted devices. The diagnosis of endocarditis is made on the basis of a well-established set of diagnostic criteria, of which echocardiography is one of the major factors. Three echocardiographic findings are important: mobile echodense mass(es) attached to valvular/mural endocardium/implanted material, fistulae/abscess formation, and/or new disruption/dehiscence of a prosthetic valve. TOE has a higher sensitivity and specificity, and is mandated where prosthetic valve endocarditis is suspected, to identify major complications and guide surgical planning.[3,18,19]

CATECHOLAMINE-INDUCED LV DYSFUNCTION

Excessive catecholamine use may result in myocardial ischaemia or Takotsubo cardiomyopathy.[32] These can be readily diagnosed using echocardiography. In addition, catecholamines may result in dynamic LV outflow tract obstruction diagnosed by demonstration of cavity/outflow tract obliteration using 2D echocardiography together with high outflow velocities on CW Doppler.[3,4]

CHEST TRAUMA[3]

There are several considerations in the ICU echocardiography in this patient population. When tamponade is suspected TTE provides a rapid diagnosis, otherwise it has a relatively low diagnostic yield compared with TOE. A wide range of abnormalities have been described following chest trauma, and where time permits a comprehensive study should be performed to diagnose/exclude: pericardial/pleural collections, aortic and mitral valve disruption, aortic disruption (high sensitivity and specificity with TOE), VSR, coronary artery disruption (ischaemia and/or fistulae) and myocardial contusion.

TAMPONADE POST-CARDIAC SURGERY[33]

Collections may accumulate rapidly, but be small, localised and difficult to demonstrate using TTE owing to persistent presence of air in the mediastinum immediately postoperatively. Diagnosis relying on TTE misses ≤50% cases, and TOE should be considered. As tamponade is a clinical diagnosis, in the presence of suggestive features re-exploration is the investigation of choice.

CONCLUSIONS

The potential scope for ICU echocardiography is huge, and expanding. In the near future, all practitioners involved in acute care will have the skills necessary for basic, focused echocardiography, in particular as US extends into the medical student curriculum.[34] Comprehensive echocardiography in the critically ill is challenging, and although cardiology-based echocardiographers may possess the full range of echocardiographic techniques, they will not necessarily have the ICU knowledge necessary to put them into clinical context. Similarly, although increasing numbers of intensivists are undergoing training in echocardiography, they may not have access to the full range of echocardiographic techniques required, although it is important to remember that the older techniques have much to offer and can be applied in a sophisticated manner within the pathophysiological context of the intensive care unit. With cardiologists returning to cardiac ICU, and intensivists embracing the technique of echocardiography, the potential for future collaborative research in this field is clear.

Oxygen therapy

Adrian J Wagstaff

In humans, uptake of environmental oxygen via the lungs provides necessary substrate for energy production. This is a key ingredient to survival. Aerobic respiration is the most efficient mechanism for adenosine triphosphate (ATP) production by oxidative phosphorylation and serves as the fuel to maintain cellular homeostasis and metabolism. Absence or lack of ATP leads to loss of cellular integrity initially followed by cellular and later organism death. A substantial part of critical care is targeted at treating and/or preventing hypoxia, yet in recent years the risks of hyperoxia leading to organ damage have become better understood. Thus an understanding of the common pathways and significance of cellular hypoxia is vital to providing appropriate and safe support and treatment to the acutely unwell patient.

PHYSIOLOGY OF OXYGEN DELIVERY

The transfer of a gas across a membrane relies on physical principles and is summarised by Fick's first law of diffusion[1]:

$$O_2 \text{ diffusion} = K \times A/T \times \Delta P \qquad (28.1)$$

where K is the diffusion constant for a particular gas, A is the surface of a membrane; T is the membrane's thickness and ΔP the difference in partial pressure across the membrane. As oxygen is poorly soluble in water, diffusion alone became insufficient to deliver oxygen to the cells, and novel methods of delivery have evolved, most notably the cardiovascular system.[2] This provided the means to deliver oxygen around the body.

OXYGEN DELIVERY

Transport of oxygen to the cells can thus be divided into six simple steps reliant only on the laws of physics: (1) convection of oxygen from the environment into the body (ventilation); (2) diffusion of oxygen into the blood (oxygen uptake): (3) reversible chemical bonding with haemoglobin; (4) convective transport of oxygen to the tissues (cardiac output): (5) diffusion into the cells and organelles; (6) the redox state of the cell. This chain of events is oxygen delivery or more correctly oxygen flux ($\dot{D}_{O_2}$).

Step 1: convection – ventilation The first step occurs in the lung in the form of pulmonary ventilation. At sea level the partial pressure of oxygen in environmental air is approximately 160 mmHg (21.3 kPa). On inspiration the air is humidified and mixed with exhaled carbon dioxide (CO_2) such that at the alveolus the P_{AO_2} is 100 mmHg (13.3 kPa). This will vary in different environments and different conditions (**Table 28.1**). Much of oxygen therapy is based on increasing oxygen delivery into the lungs whether by masks or other devices.

Step 2: diffusion – alveolus to blood Oxygen within the alveolus diffuses across the alveolar–capillary membrane. The average thickness of the alveolar capillary membrane is 0.3 µm and the surface area of the respiratory membrane between 50 and 100 m^2. This leads to a Pa_{O_2} in the pulmonary capillaries of approximately 90 mmHg (12 kPa). Herein lies many of the problems seen in the critically ill where two mechanisms predominate: (1) the thickness and barrier effect of the space between alveolus and capillary – usually a minor issue, and (2) the relationship between perfusion and ventilation at alveolar level (V/Q ratio) – in ARDS intrapulmonary shunt is the predominant cause of hypoxaemia.

Step 3: haemoglobin binding Oxygen is poorly soluble in water, having a solubility of 0.003082 g/100 g H_2O. Having diffused across the alveolar capillary membrane, the oxygen binds rapidly to the respiratory pigment haemoglobin. The saturation of haemoglobin with oxygen (Sa_{O_2})$:P_{O_2}$ relationship is not linear and forms a sigmoidal shape (**Fig. 28.1**). The P50 is the Pa_{O_2} at which 50% of the haemoglobin is saturated. Various factors are known to alter the affinity of haemoglobin for oxygen (**Table 28.2**). These have teleological advantages as for example, a low pH or high CO_2 at tissue level could imply tissue hypoxia, and the reduction in oxygen-binding affinity increases oxygen availability. Similarly hyperthermia (fever), hypercarbia and an increase in the concentration of 2,3-diphosphoglycerate (2,3 DPG) all move the curve to the right and increase oxygen availability. 2,3-DPG is a by-product of glycolysis and therefore binds haemoglobin in predominantly hypoxic tissues, facilitating a release of oxygen. Conversely hypocarbia, alkalosis and low concentrations of 2,3-DPG result in a leftward shift of the curve and a

Table 28.1 Clinical significance of some Pa_{O_2} and Sa_{O_2} values

Pa_{O_2}		Sa_{O_2}	
MMHG	*KPA*	*(%)*	CLINICAL SIGNIFICANCE
160	20.0	99	Inspired air at sea level
97	12.9	97	Young normal man
80	10.6	95	Young normal man asleep Old normal man awake Inspired air at 19000 ft (5800 m)
70	9.3	93	Lower limit of normal
60	8.0	90	Respiratory failure (mild); shoulder of O_2 dissociation curve
50	6.7	85	Respiratory failure (significant); admit to hospital
40	5.3	75	Venous blood – normal Arterial blood – respiratory failure (severe). Acclimatised man at rest at 9000 ft (2750 m)
30	4.0	60	Unconscious if not acclimatised
26	3.5	50	P50 of haemoglobin
20	2.7	36	Acclimatised mountaineer exercising at 19000 ft (5800 m); hypoxic death

higher affinity for binding for any given P_{O_2}. Systemic interventions such as alteration in P_{CO_2} or pH will influence the curve and therefore oxygen dissociation and availability.

Step 4: convection – cardiovascular In humans the cardiovascular system is the solitary delivery system of

Table 28.2 Factors influencing the position of the oxygen dissociation curve

FACTORS INCREASING P50 (CURVE SHIFTS TO THE RIGHT)	FACTORS DECREASING P50 (CURVE SHIFTS TO THE LEFT)
Hyperthermia	Hypothermia
Decreased pH (acidaemia)	Increased pH (alkalaemia)
Increased P_{CO_2} (Bohr effect)	Decreased P_{CO_2}
Increased 2,3 DPG	Decreased 2,3 DPG Fetal haemoglobin Carbon monoxide Methaemoglobin

oxygen to the cells. This is achieved by the convection (bulk flow) of oxygen, predominantly bound to haemoglobin (21 mL/100 mL) from the lungs via the heart and out into the systemic circulation by way of the arteries. These branch down to form the capillaries where the oxygen is offloaded to the tissues. Convection of oxygen by the cardiovascular system is influenced centrally by the cardiac output (CO) and peripherally by local control of the regional perfusion of the tissues.

Oxygen delivery also relies on its concentration in the blood (Ca_{O_2}). This is calculated by the formula[3]:

$$Ca_{O_2} = (\mathrm{Hb(g/dL)} \times 1.39 \times Sa_{O_2}(\%)) + (0.003 \times Pa_{O_2}) \tag{28.2}$$

Each gram of haemoglobin binds 1.39 mL of oxygen. Thus changes in Sa_{O_2} and haemoglobin concentration are important in determining the oxygen concentration. Delivery of oxygen is therefore summarised by the formula:

$$\begin{aligned} &\text{delivery of oxygen } (\dot{D}_{O_2})\ \mathrm{mL/min} \\ &\quad = 10 \times \mathrm{CO\ (L/min)} \times Ca_{O_2} \end{aligned} \tag{28.3}$$

Normal resting $\dot{D}_{O_2}$ is approximately 1000 mL/min. Oxygen consumption ($\dot{V}_{O_2}$) at rest is about 250 mL/min:

$$\begin{aligned} &\text{oxygen consumption } (\dot{V}_{O_2})\ \mathrm{mL/min} \\ &\quad = 10 \times \mathrm{CO\ (L/min)} \times (Ca_{O_2} - C\bar{v}_{O_2}) \end{aligned} \tag{28.4}$$

where $C\bar{v}_{O_2}$ is calculated as $(1.39 \times [\mathrm{Hb}] \times S\bar{v}_{O_2}) + (0.003 \times P\bar{v}_{O_2})$. It can be seen that the amount of oxygen extracted is about 25% of that delivered at rest and that there is a large reserve. This obviously varies between organs. This ratio is referred to as the oxygen extraction ratio: $\mathrm{OER} = \dot{V}_{O_2}/\dot{D}_{O_2}$.

During exercise this can increase by up to 70–80% at maximum. Oxygen that is not removed by the tissues returns to the heart and lungs. Globally the difference between that delivered and that returning is the consumption. This model can also be used to look at regional consumption. Hence the saturation of mixed venous blood ($S\bar{v}_{O_2}$) which is all the returning blood, or

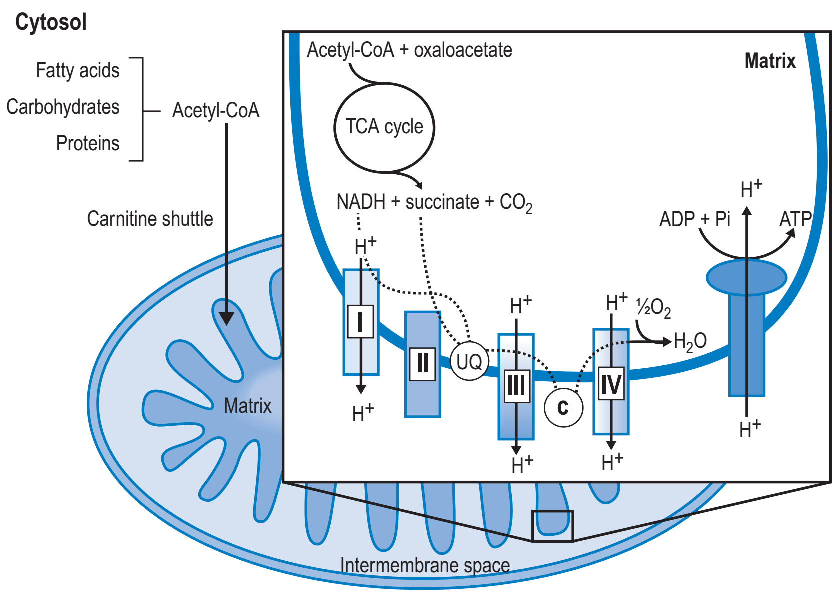

Figure 28.2 Schematic representation of the mitochondrion. Detail of the electron transport chain within the inner mitochondrial membrane is shown. *(After van Boxel[4].)*

central venous blood (most of the returning blood), can be used as an indicator of global $\dot{V}_{O_2}$ and indirectly the adequacy of $\dot{D}_{O_2}$. If oxygen delivery by the microcirculation and cellular oxygen uptake are adequate, then a $S\bar{v}_{O_2}$ value of 65% usually indicates that global $\dot{D}_{O_2}$ is appropriate. Lower values may indicate increased uptake, but more often reduced or inadequate delivery. Mixed venous blood is useful for measurement of global $\dot{D}_{O_2}$, but it usually requires the presence of a pulmonary artery catheter. The use of central venous saturations has become an alternative surrogate that is usually adequate and considerably more practical. The body cannot store large amounts of oxygen (although the lungs and myoglobin can act as short-term reservoirs) so is dependent on a continuous supply. The excess ability to increase $\dot{D}_{O_2}$ to match changes in $\dot{V}_{O_2}$ is an adaptation that permits sudden changes in demand, such as exercise where $\dot{V}_{O_2}$ can sometimes exceed 1500 mL/min.

Step 5: diffusion – blood to mitochondrion Ninety per cent of cellular aerobic metabolism takes place in the mitochondria. The rate of diffusion of oxygen from bound oxyhaemoglobin to the mitochondria follows similar principles to the diffusion of oxygen into the blood from the alveoli: (1) Fick's law of diffusion, where ΔP depends on $\dot{D}_{O_2}$ and the rate of cellular uptake and utilisation, and (2) the position of the oxygen haemoglobin dissociation curve. Once delivered to the cell, oxygen generates ATP by the electron transport chain, utilising the reducing power of NADH and $FADH_2$ generated from the citric acid cycle.[4] The movement of electrons through the chain requires a terminal electron acceptor. This is molecular oxygen, which combines with the electrons and protons to form water. Without oxygen, the proton motive force generated by the electron chain would not exist and phosphorylation of ADP to ATP would cease (**Fig. 28.2**).[5]

Originally at approximately 160 mmHg (21.3 kPa), the partial pressure of oxygen (P_{O_2}) at the mouth can fall to as low as 1 mmHg (0.133 kPa) in some mitochondria. Below this value, cellular demands for oxygen outweigh its delivery, and ATP production may be reduced.

Step 6 – the redox state of the cell Oxygen delivery from atmosphere to cell is conventionally considered a cascade, implying that a high concentration at one end cascades down and increases oxygen in the cell. Though this will increase oxygen potentially available to the cell, the driving force for it to enter the cell and mitochondrion is the gradient between the partial pressures of oxygen within and outside the cell. Increased oxygen utilisation reduces that tension and increases that gradient; conversely, adequate oxygen in the cell will reduce the gradient until oxygen will not diffuse. Hence the cell itself determines how much oxygen it uses by creating the gradient that 'sucks in' oxygen – and not a cascade. Similarly it is the ATP/ADP ratio and probably hydrogen ion concentration that drives ATP production and modifies oxygen requirement (i.e. the cell is largely autonomous and uses what it needs).[6] Whereas adequate oxygen delivery is important, excess oxygen is at least theoretically of no benefit.

PATHOLOGY OF OXYGEN DELIVERY ($\dot{D}_{O_2}$)

Failure of oxygen delivery to the cells leads rapidly to cellular dysfunction, and can lead to cellular death and

organ dysfunction culminating in the organism's death. $\dot{V}_{O_2}$ drives the $\dot{D}_{O_2}$ requirement, and failure of $\dot{D}_{O_2}$ to match $\dot{V}_{O_2}$ results in reduction in aerobic metabolism and energy production, necessitating ATP production by the less-efficient glycolytic pathway. The level of $\dot{D}_{O_2}$ at which $\dot{V}_{O_2}$ begins to decline has been termed the 'critical $\dot{D}_{O_2}$' and is approximately 300 mL/min in an adult (**Fig. 28.3**).[7] 'Shock' is the usual term used in this situation, defined loosely as failure of delivery of oxygen to match the demand of tissue. Commonly this refers to failure of the circulation, but low $\dot{D}_{O_2}$ can result from several pathological mechanisms that can occur singly or in combination (**Table 28.3**).

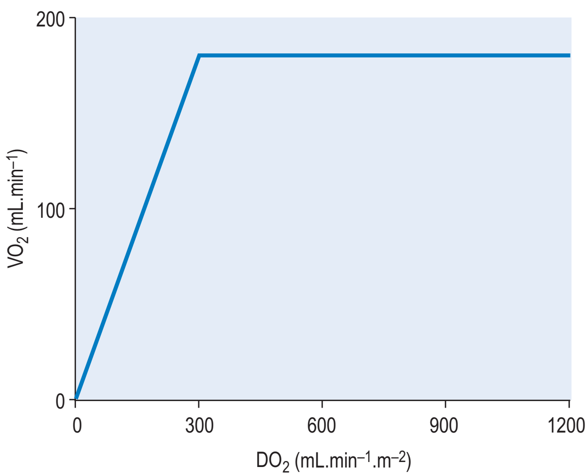

Figure 28.3 The normal relationship between $\dot{V}_{O_2}$ and $\dot{D}_{O_2}$. Above the value of 'critical $\dot{D}_{O_2}$' $\dot{V}_{O_2}$ is independent of oxygen delivery. Below this value and $\dot{V}_{O_2}$ becomes supply dependent and may be amenable to therapeutic interventions.

The impact of a low $\dot{D}_{O_2}$ can be worsened by increased oxygen demand. The metabolic rate increases with exercise, inflammation, sepsis, pyrexia, thyrotoxicosis, shivering, seizures, agitation, anxiety and pain.[8] Therapeutic interventions such as adrenergic drugs (e.g. epinephrine[9]) and certain feeding strategies can also lead to and increased $\dot{V}_{O_2}$. In critical illness, where oxygen delivery is considered to be in jeopardy, there has been considerable interest in the relationship between $\dot{D}_{O_2}$ and $\dot{V}_{O_2}$ (see Fig. 28.3). The presence of signs or markers of tissue hypoxia such as acidosis imply inadequate tissue oxygenation. This could be from either inadequate delivery failing to meet consumption requirements or reduced ability of the tissues to extract oxygen. The former could be corrected by increasing delivery; the latter is more difficult. Historically this has led to the strategy for delivering 'supranormal' $\dot{D}_{O_2}$ to ensure adequate supply.[10,11] It is irrefutable that if delivery is inadequate it should be corrected to meet consumption, but unless different measurement techniques are used mathematical linkage occurs so as one increases so does the other.[12,13] Further, the inotropes used to increase delivery also increase consumption. As discussed later, hyperoxia also has directly detrimental effects.

Clinical studies clearly show that adequate resuscitation to meet oxygen requirements is sensible. In the critically ill going beyond this is not helpful[14,15] although there may still be a place for supra-optimal values in the high-risk surgical patient.[10,11] In the acute situation the combined use of markers of tissue hypoxia, such as acidosis and lactate in conjunction with surrogates of oxygen delivery such as Scv_{O_2} and standard haemodynamic measurements of an adequate circulation, have proved beneficial.[16,17] So-called early goal-directed therapy is now included in published and recently updated guidelines for the treatment of severe sepsis

Table 28.3 Types of hypoxia

TYPE OF HYPOXIA	PATHOPHYSIOLOGY	EXAMPLES
Hypoxic hypoxia	Reduced supply of oxygen to the body leading to a low arterial oxygen tension	1. Low environmental oxygen (e.g. altitude) 2. Ventilatory failure (respiratory arrest, drug overdose, neuromuscular disease) 3. Pulmonary shunt: (a) anatomical – VSD with R–L flow (b) physiological – pneumonia, pneumothorax, pulmonary oedema, asthma
Anaemic hypoxia	The arterial oxygen tension is normal, but the circulating haemoglobin is reduced or functionally impaired	Massive haemorrhage, severe anaemia, carbon monoxide poisoning, methaemaglobinaemia
Stagnant hypoxia	Failure of transport of sufficient oxygen due to inadequate circulation	Left ventricular failure, pulmonary embolism, hypovolaemia, hypothermia
Histotoxic hypoxia	Impairment of cellular metabolism of oxygen despite adequate delivery	Cyanide poisoning, arsenic poisoning, alcohol intoxication

Table 28.4 Early goal-directed therapy: a summary of D_{O_2} parameters set to achieve in first 6 hours of the diagnosis of severe sepsis with associated hypotension and a plasma lactate concentration of ≥4 mmol/L

VARIABLE	PARAMETERS
Arterial oxygen saturation (Sa_{O_2})	≥93%
Central venous pressure (CVP)	8–12 mmHg (1.06–1.6 kPa)
Mean arterial pressure (MAP)	65–90 mmHg (8.65–11.97 kPa)
Urine output (UO)	≥0.5 mL/kg/h
Mixed venous oxygen saturations (Sv_{O_2}) or central venous oxygen saturations (Scv_{O_2})	≥70%
Haematocrit	≥30%

After Rivers et al.[16]

(**Table 28.4**).[18] The benefits of this new approach may well have as much to do with the prompt and aggressive improvements in haemodynamics and resuscitation as the values obtained. Timing is probably the significant difference compared with other applications of the 'supranormal' technique. Targeted oxygen delivery is a major debate that is still evolving (**Box 28.1**). Oxygen delivery can be improved in a variety of ways from the ambient inspired oxygen through the lungs and cardiovascular system to the cell itself, but once at the cell the ability to manipulate delivery ceases.

CELLULAR HYPOXIA

In environments where the $\dot{D}_{O_2}$ is reduced, human cells can tolerate hypoxia to a certain extent by adapting 'hibernation' strategies to reduce metabolic rate, increased oxygen extraction from surrounding tissues and enzyme adaptations that allow continuing metabolism at low P_{O_2}.[19] Anaerobic metabolism is actively utilised by some tissues. In low oxygen concentrations, both myocardial and vascular endothelium up-regulate glycolytic enzymes and glucose transport proteins.[20] Research performed in humans at altitude in order to mimic hypoxic stress suggests that, though $\dot{D}_{O_2}$ is preserved, $\dot{V}_{O_2}$ is reduced.[21] This may be due to reduced oxygen uptake at a microcirculatory level, reduced cellular oxygen consumption or an improvement in the efficiency of ATP production. These theories may be evidenced by the recovery of critical illness multi-organ failure, in which function may be compromised in the short term without long-term structural damage,[22] and in vitro studies of mitochondria, which demonstrate more efficient ATP production when exposed to hypoxic environments.[23] The ability of humans to tolerate and then acclimatise to altitude mainly by a reduction in $\dot{V}_{O_2}$ may explain why many critical care strategies

Box 28.1 Summary of targeted oxygen delivery

Goal-directed therapy
- Supraoptimal values in the critically ill – not recommended
- Perioperative optimisation with supranormal values – possibly useful but controversial
- Resuscitation against markers of peripheral oxygen use such as Scv_{O_2} and lactate (early goal-directed therapy) – currently advocated

to increase Pa_{O_2} (e.g. inhaled nitric oxide) fail to convey any survival benefit. Indeed, accepting a Pa_{O_2}/Sa_{O_2} below 'normal' levels does not appear to significantly reduce survival and may reduce the risk of oxygen toxicity.[23]

REGIONAL HYPOXIA

Much of what has been discussed describes effects of oxygen delivery and uptake for the body as a whole. The reality is far more complex, as not only can the $\dot{D}_{O_2}$ of each organ system be manipulated to meet demand, but also, within each organ, regional demands may vary and can be varied. Few of the clinical methods commonly used for assessing $\dot{D}_{O_2}$ can identify changes in either organ or regional $\dot{D}_{O_2}$. Thus it is possible in critical illness for tissue hypoxia to exist with associated organ dysfunction despite normal global $\dot{D}_{O_2}$ and $S\bar{v}_{O_2}$ values.[24]

The effects of disordered or diverted regional blood flow can be important. For example, in shock splanchnic blood flow is often reduced, with the potential for ischaemia. Clearly detection of gut ischaemia could be used to influence management of oxygen delivery and hopefully reduce the likelihood of multi-organ failure.[25] The control of regional blood flow is itself complex. Methods of increasing global $\dot{D}_{O_2}$ in the hope that this will optimise all tissues often necessitates the use of vasoactive drugs (vasopressors, inotropes and vasodilators). Paradoxically, although such therapy can influence regional flow it may not necessarily be in the direction sought in individual regions.

DIAGNOSIS AND MONITORING OF $\dot{D}_{O_2}$

Early recognition and treatment of oxygen delivery failure is important for preserving organ function.[16] Clinical assessment of $\dot{D}_{O_2}$ and $\dot{V}_{O_2}$ (e.g. heart rate, blood pressure or urine output) can be misleading. Particularly in the young patient, the ability of the OER increase to as high as 70–80% can mean that such variables can change only late in the evolution of diminished $\dot{D}_{O_2}$. However, the assessment of an effective cardiac output (ECO) – normal heart rate, blood pressure and peripheral perfusion with signs of organ function and normal oxygen saturation – must not be excluded in favour

of more technical quantitative methods. Rather, the technical values must be considered in the clinical context. All assessments of $\dot{D}_{O_2}$, clinical or technical, require continuous re-evaluation to ensure that treatments being planned or administered are appropriate for the patient's current condition.

Sa_{O_2} AND Pa_{O_2}

Both these measures are included in the Ca_{O_2} equation (28.2), and their importance is clear. However, what is a 'safe' Sa_{O_2} and/or Pa_{O_2} can be difficult to define. Measured systemically, they do not alone reflect tissue oxygenation, and oxygen extraction mechanisms vary between organs. In general, however, supplementary oxygen is required when Pa_{O_2} falls below 60 mmHg (8 kPa) or the Sa_{O_2} is below 88%. Table 28.1 lists the clinical significance of common Pa_{O_2} and Sa_{O_2} values.

ACID–BASE BALANCE

Many intensive care units use acid–base balance as a simple bedside indicator of global $\dot{D}_{O_2}$. The presence of acidosis and a base deficit of less than –2 may be used to detect evidence of inadequate $\dot{D}_{O_2}$ presuming this reflects lactate accumulation. However, plasma lactate concentration is an unreliable indicator of tissue hypoxia; it represents the balance between production and consumption so if used in isolation or as a single value to assess $\dot{D}_{O_2}$ can easily mislead.[26] The use of lactate as a marker of $\dot{D}_{O_2}/\dot{V}_{O_2}$ balance is best used as a trend using serial measurements.

$S\bar{v}_{O_2}/Scv_{O_2}$

In critical illness a falling $\dot{D}_{O_2}$ can be compensated for by an increase in oxygen extraction. This leads to a lower oxygen saturation of haemoglobin returning to the right side of the heart. Analysis of this saturation either in vivo (fibreoptic oximetry) or in vitro (oximetry) allows assessment of the OER. Classically, a low $S\bar{v}_{O_2}$ (< 70%) in the face of a normal Sa_{O_2}, implies tissue hypoperfusion secondary to a low CO, either hypovolaemia or pump failure. It could, however, indicate very high $\dot{V}_{O_2}$ as may occur with hyperthermia. Conversely a raised $S\bar{v}_{O_2}$ (> 75%) will imply low demand (e.g. hypothermia, or a cellular utilisation problem), easily explained in cyanide poisoning when the oxidative phosphorylation mechanism is inhibited, but much more difficult to rationalise when seen (commonly) in sepsis. In a very low output state it could indicate total failure of peripheral perfusion and therefore no oxygen usage. Scv_{O_2} is a reasonable surrogate for $S\bar{v}_{O_2}$ and reduces the need for the more complex pulmonary artery catheter.[17,27] Whichever method of venous oxygen saturation is used, it must be in conjunction with other markers of adequacy of oxygen delivery and clinical context, as outlined in Table 28.4.

MEASUREMENT OF REGIONAL $\dot{D}_{O_2}$

Most assessments of $\dot{D}_{O_2}$ are global and do not reflect regional differences between organs or even different tissues within an organ. Current methods of non-invasively assessing individual organ or tissue oxygenation are limited; measurements are difficult, require specialised techniques and are not widely available. Currently only gastric tonometry and near-infrared spectroscopy (NIRS) have clinical applications in the detection of organ hypoxia.[25] Novel techniques such as palladium porphyrin phosphorescence-based techniques are being evaluated in animals, but require improvement as palladium is itself cytotoxic.[28] Cellular oxygenation measurement methods are also in development.[29]

OXYGEN THERAPY APPARATUS AND DEVICES

In the hypoxic self-ventilating patient, delivery of oxygen to the alveoli is usually achieved by increasing the environmental oxygen fraction (Fi_{O_2}). Most commonly this involves the application of one of the many varieties of oxygen mask to the face, such that it covers the nose and mouth. There are other methods (e.g. nasal cannulae), but each needs to fulfil the same basic requirements.

Most of the simpler devices (e.g. plastic masks, nasal cannulae) deliver oxygen at relatively low oxygen flow rates relative to peak inspiratory flows (25–100+ L/min). The final Fi_{O_2} delivered is heavily influenced by the entrainment of environmental air, which dilutes the set Fi_{O_2}. From a physical principle perspective, the actual concentration of oxygen delivered is determined by the interaction between the delivery system and the patient's breathing pattern. The Fi_{O_2} that reaches the alveolus is therefore unpredictable. Factors that influence this can broadly be divided up into patient factors and device factors (**Box 28.2**).[30]

In the hypoxic patient it is common to find significant increases of inspiratory flow rates as well as an absence of the respiratory pause. This can result in the actual Fi_{O_2} at the alveolus being significantly less than that thought to be delivered. This is due to a greater proportion of the inhaled gas being entrained air when the patient's inspiratory flow rate increases. The normal peak inspiratory flow rate (PIFR) is 25–35 L/min; in

Box 28.2 Factors that influence the Fi_{O_2} delivered to a patient by oxygen delivery devices[30]

Patient factors	Device factors
Inspiratory flow rate	Oxygen flow rate
Presence of a respiratory pause	Volume of mask
Tidal volume	Air vent size
	Tightness of fit

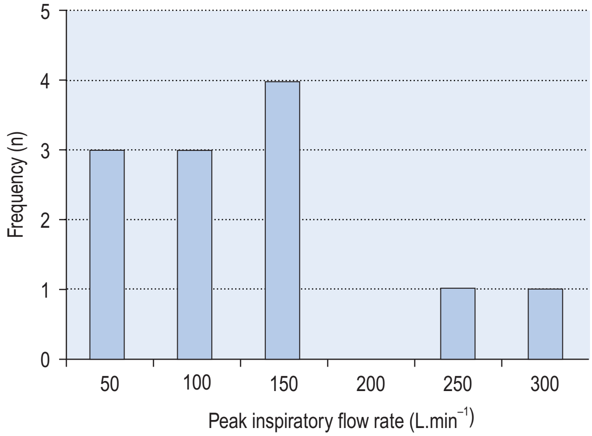

Figure 28.4. Spirometric peak inspiratory flow rates (PIFR) taken from a group of 12 critical care patients with respiratory distress and hypoxia. Most of the patients have a PIFR below 150 L/min. However, two patients exceed 200 L/min. This will have a negative effect on the concentration of oxygen delivered from a variable performance system (e.g. Hudson).[30]

critical illness this can increase eightfold (**Fig. 28.4**).[31] The greater the inspiratory flow rate, the lower is the alveolar Fi_{O_2}. This is particularly true for the variable performance-type masks, but is seen even in the more 'reliable' Venturi-type masks particularly when higher Fi_{O_2} inserts are used. The presence of a valve-controlled reservoir bag on a 'non-rebreather' semi-rigid plastic mask should compensate for high inspiratory flows – hence the belief that such masks can deliver 100% oxygen. This is not the case though, and in models of human ventilation such masks do not seem to confer significant extra oxygen delivery ability above that of semi-rigid plastic masks without a reservoir bag (**Figs 28.5** and **28.6**).[32] The failure of oxygen masks to deliver the desired Fi_{O_2} can be improved either by having a high enough oxygen flow rate and reservoir to compensate for the high inspiratory flow rate e.g. high-flow nasal cannulae such as the Vapotherm®, or by sealing the upper airway (nose and mouth) from the environment (e.g. the CPAP mask). Indeed, there is evidence supporting the hypothesis that some of the improvement in oxygenation seen with CPAP ventilation may be due to the eradication of entrainment of environmental air rather than the positive airway pressure exerted by the CPAP valve.[32]

In summary, the use of non-sealing oxygen masks and cannulae should be guided by the patient's requirements and response to therapy, rather than a belief that the concentration being delivered is that reaching the alveolus. This can be particularly important in the treatment of patients whose ventilatory drive is sensitive to P_{O_2} levels.

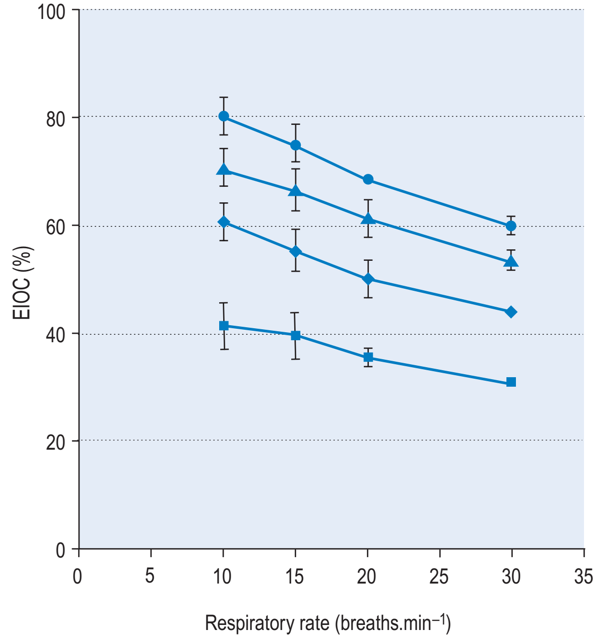

Figure 28.5 The performance of a Hudson mask on a model of human ventilation at a tidal volume of 500mLs and four oxygen flow rates (2 L/min (□), 6 L/min (◇), 10 L/min (△) and 15 L/min (○)). As the respiratory rate increases, the effective inspired oxygen concentration (EIOC) deteriorates.[31]

OXYGEN DELIVERY DEVICES

Methods of delivering oxygen to conscious patients with no instrumentation to their airway can broadly be divided into four categories: (1) variable performance systems, (2) fixed performance systems, (3) high-flow systems, and (4) others. With the exception of the intravascular devices, all comprises similar component parts:

1. *Oxygen supply:* oxygen can be delivered from pressurised cylinders, hospital supply from cylinder banks or a vacuum-insulated evaporator (VIE), or an oxygen concentrator.
2. *Oxygen flow control:* oxygen supplied to the device is controlled by some sort of valve, often with an associated flow meter (e.g. OHE ball valve flow meter).
3. *Connecting tubing:* both from the supply to the flow control and from the flow control to the device, the type and size of the tubing are important. Small-bore tubing can limit oxygen flow when high flow is intended. In some systems the connecting tubing can also act as a reservoir – e.g. Ayre's T-piece. Some devices require specialised tubing with appropriate end attachments – such as the Schräeder valves required for connecting to the wall oxygen supply.

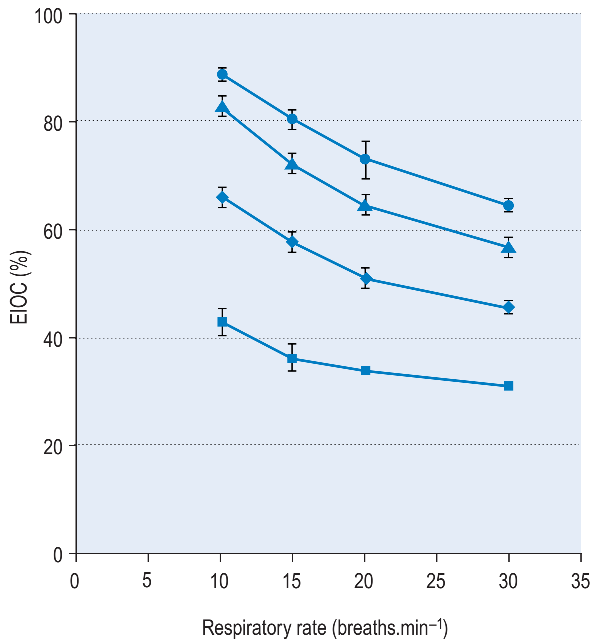

Figure 28.6 The performance of a Hudson non-rebreather mask on a model of human ventilation at a tidal volume of 500 mL and four oxygen flow rates (2 L/min (□), 6 L/min (◇), 10 L/min (△) and 15 L/min (○)). As the respiratory rate increases, the effective inspired oxygen concentration (EIOC) deteriorates. Note also how the curves of the graph are similar to the Hudson mask without the reservoir bag, implying no superiority with its addition.[31]

4. *Reservoir:* all oxygen delivery devices have some sort of reservoir. In a simple oxygen mask it is the mask itself. Some low-flow CPAP circuits have a balloon reservoir. The nasal cannulae utilise the nasopharynx as a reservoir. An oxygen tent uses the volume of the tent as a large reservoir. The effectiveness of the reservoir in 'storing' oxygen ready for the next inspiratory effort is one of the important factors in governing its ability to deliver the desired oxygen concentration. The oxygen tent is a good example of the effectiveness of a large reservoir, as it eliminates air entrainment whatever the patient's PIFR. Thus the oxygen flow rate does not have to be high, but just enough to ensure that CO_2 re-breathing is abolished. Indeed it is the retention of CO_2 that can be the major problem if gas is expired into the reservoir.
5. *Patient attachment:* the patient is connected to the oxygen supply and reservoir such that the device delivers oxygen to the airway – either by directly covering the upper airway (e.g. plastic mask/head box), intranasally, or by increasing the oxygen concentration in the wider environment as in an oxygen tent.
6. *Expired gas facility:* expired gas from the patient needs to be allowed to dissipate into the environment, and not be retained in the system to be inspired at the next inspiratory effort. Most masks achieve this by having a small reservoir capacity and holes in the plastic to allow the gas to exit. One-way valves, as in the non-rebreather type reservoir mask, aid in unidirectional flow of gas away from the patient. High-flow T-piece systems like those used in a CPAP system utilise the high flow to remove the gas down an expiratory limb and into the environment.
7. *Humidification:* most systems use the physiological humidification properties of the nasopharynx and trachea. However, high-flow systems may overcome this leading to drying of the airway and secretions, which can be uncomfortable and undesirable. Artificial humidification (and warming) should be employed using devices such as a water bath or heat and moisture exchanger (HME).
8. *Oxygen monitor:* some systems have an oxygen monitor incorporated in the apparatus (e.g. a fuel cell). This allows the much more accurate monitoring of F_{IO_2}, but this is dependent on where in the system it is placed, and also adds bulk and expense to the oxygen delivery method.

VARIABLE PERFORMANCE SYSTEMS

Typically these are non-sealed mask or nasal cannulae systems, which deliver oxygen at low gas flows (2–15 L/min). The reservoir is usually small, consisting of the volume of the mask in the case of the semi-rigid type, or the nasopharynx as in the nasal cannulae. The entrainment of environmental air is important in their delivery capability and has to be considered when being used.

Nasal cannulae The proximity of the reservoir – the nasopharynx – means that these systems are particularly sensitive to changes in inspiratory flow rate and particularly the loss of the respiratory pause. However for mild hypoxia, they are tolerated well by patients who can eat and drink with them in situ. They can cause drying of the nasal mucosa when used at higher flow rates, and newer systems are available that can humidify and warm the inspired oxygen. They are cheap and easy to use with no risk of CO_2 retention.

Simple semi-rigid plastic masks (e.g. Hudson, MC) The most commonly used type of oxygen mask, these are cheap and easy to administer. The reservoir comprises the mask, and rebreathing of CO_2 can therefore occur if used at oxygen flow rates below 4 L/min. A maximum F_{IO_2} of only 0.6–0.7 can be achieved, which will be lower in the presence of respiratory distress.

Tracheostomy masks These semi-rigid plastic masks act in the same way as their facial counterparts. However, the delivery they achieve is very dependent on the presence of an endotracheal tube and the inflation status of its cuff. If absent or if the cuff is deflated then air from

the nasopharynx will mix with that being delivered to the tracheostomy, and further dilute the Fi_{O_2}.

T-piece system These simple systems, consisting of an inspiratory limb and expiratory limb forming the bar of the 'T', can be used with endotracheal tubes (oral, nasal or tracheostomy) or with a sealed CPAP-type mask. The oxygen flow rate needs to be high enough to match the patient's PIFR so as to prevent rebreathing of expired gas and thus potential entrainment of air from the expiratory limb. The seal of the mask or tube cuff is important also to prevent entrainment of air.

FIXED PERFORMANCE SYSTEMS

These systems are so called because their delivery of oxygen is independent of the patient factors outlined above.

Venturi-type masks Oxygen concentration is determined by the Venturi principle: oxygen passing through a small orifice entrains air to a predictable dilution. The Fi_{O_2} is adjusted by changing the Venturi 'valve' and setting the appropriate oxygen flow rate. Although the Venturi effect can deliver 40–60 L/min, this is possible only at the lower Fi_{O_2} valves (e.g. at Fi_{O_2} of 0.24 the flow rate is approximately 53 L/min at an inflow of 2 L/min), and oxygen flow rate falls as the Fi_{O_2} increases. Thus, in respiratory distress associated with hypoxia, the reduction in oxygen flow rate can lead to failure despite a higher Fi_{O_2} setting. The larger orifice leads to the system behaving more like a simple mask.

Anaesthetic breathing circuits Non-rebreathing systems have one-way valves (e.g. Ambu-bag) and usually closed mask systems so they deliver what is set. Non-rebreathing systems (e.g. Mapleson A, B, C, D and E) depend on the gas flows to ensure no rebreathing. No air entrainment is possible but rebreathing occurs readily at low flows (most require flows > 150 mL/kg).

HIGH-FLOW SYSTEMS

As alluded to above, the T-piece system can act as a fixed-performance system if the oxygen flow rate is sufficiently high. Other high-flow systems exist (e.g. Vapotherm®) that use flow rates up to 30 L/min nasally. They require humidification and heating of the inspired gas to allow patient tolerance.

Positive-pressure devices Non-invasive positive pressure (NIPPV) delivers oxygen with some element of positive pressure exerted during the respiratory cycle. It does not require instrumentation of the airway, and is delivered either by tight fitting mask to the face, nose or as a helmet. The simplest CPAP system is a T-piece with a positive-pressure valve attached to the expiratory limb, as with a Mapleson E system. Other methods are also available; some utilise a balloon reservoir rather than a high-flow oxygen generator (Mapleson A). CPAP helps improve functional residual capacity and compliance.[34] There is no air entrainment, which contributes to the initial rapid improvement. Theoretically the positive pressure aids alveolar recruitment. A potential problem with the T-piece CPAP systems is that the oxygen flow rate has to be adjusted to the patient's PIFR so as to prevent closure of the valve, increasing the inspiratory work of breathing. Other methods of non-invasive positive-pressure ventilation such as bilevel positive airway pressure (BIPAP) deliver oxygen at flows that should match the patient's demand.

OTHER METHODS OF OXYGEN DELIVERY

Intravascular oxygenation has been used, but not extensively – particularly in the self-ventilating patient population. Extracorporeal membrane oxygenation (ECMO) supporting the lung has recently grown in use secondary to a landmark study and recent influenza pandemics.[35,36]

MANAGEMENT OF OXYGEN THERAPY

In the correct situations, oxygen is a life-saving drug/therapy. It remains part of the initial resuscitation and ongoing management of the critically unwell. In the UK at any one time 15–17% of all hospital inpatients will be receiving oxygen.[37] However, oxygen can have detrimental effects in certain patient groups and/or situations and this may result in significant morbidity or mortality. In the UK, the British Thoracic Society published guidelines for the emergency use of supplemental oxygen in 2008 and, to date, these remain the most comprehensive.[38]

RESPIRATORY FAILURE

Identifying patients that require oxygen therapy is vital. Supplemental oxygen is required to treat most causes of hypoxia, yet different patient groups may have different resting oxygen concentrations. For example, patients with cyanotic heart disease or chronic neuromuscular disorders may have a Sa_{O_2} of 80%, yet have adapted to tolerate these oxygen tensions. The normal values of Pa_{O_2} and Sa_{O_2} in healthy volunteers are summarised in **Table 28.5**.[39] In many cases of critical illness, low oxygen tensions are due to hypoxic hypoxia. This may be as a result of reduced environmental oxygen such as that seen at altitude, pulmonary oedema or pneumonia resulting in ventilation–perfusion mismatch and intrapulmonary shunt. This is so called Type I respiratory failure where ventilation is intact, but gas transfer or haemoglobin saturation is impaired. It is defined as a Pa_{O_2}<8kPa (60 mmHg) with a normal or low Pa_{CO_2}.[39] Broadly speaking, hypoxia in any of these situations will be improved by increasing inhaled oxygen concentrations. However, caution must be taken when dealing with ventilatory or Type II respiratory failure. The differentiation of the two types of respiratory failure is made using the Pa_{CO_2}. The normal value is 4.6–6.1kPa (34–46 mmHg) and hypoxic patients with Pa_{CO_2} concentrations above this range should be considered as being in Type II respiratory failure. Many

Table 28.5 Mean (SD) Pa_{O_2} and Sa_{O_2} values (with range) in kPa and mmHg. Values shown for seated healthy men and women, non-smoking volunteers at sea level[39]

AGE (YEARS)	MEAN Pa_{O_2} (kPa and mmHg)	RANGE ±2SD Pa_{O_2} (kPa and mmHg)	MEAN Sa_{O_2} (%)	Sa_{O_2} ±2 SD
18–24	13.4 (0.71) 99.9 (5.3)	11.98–14.82 89.3–110.5	96.9 (0.4)	96.1–97.7
25–34	13.4 (0.66) 99.8 (4.9)	12.08–14.72 90–109.6	96.7 (0.7)	95.3–98.1
35–44	13.18 (1.02) 98.3 (7.6)	11.14–15.22 83.1–113.5	96.7 (0.6)	95.5–97.9
45–54	13.0 (1.07) 97 (8)	10.86–15.14 81–113	96.5 (1)	94.4–98.5
55–64	12.09 (0.6) 90.2 (4.5)	10.89–13.29 81.2–99.2	95.1 (0.7)	94.5–97.3
>64	11.89 (1.43) 88.7 (10.7)	9.02–14.76 67.3–110.1	95.5 (1.4)	92.7–98.3

causes of ventilatory failure are not affected by the oxygen tension in the blood (e.g. Guillain–Barré, opioid overdose). However, with commoner causes such as acute exacerbations of chronic obstructive pulmonary disease (COPD) and acute severe asthma, the patient's ventilation can be sensitive to oxygen therapy.

TARGETED OXYGEN THERAPY

The need for oxygen to prevent tissue hypoxia and cellular dysfunction is clear. However, it is not possible to define a single level of hypoxaemia that is dangerous to all patients. Some patients with chronic lung disease may be accustomed to living with an Sa_{O_2} of 80%, whereas others with acute organ failure may be harmed by short-term exposure to an Sa_{O_2} of < 90%.[38] So the level of hypoxaemia has to be given context not just in severity, but also in time and evidence of negative physiological effect. There is no evidence that saturations above normal result in benefit. Rather, hyperoxia can have adverse effects. As a rule of thumb, maintaining Sa_{O_2} above 90% in critically ill patients is considered best practice, and permits a margin of error.[38,40,41] Those patients at risk of hypercapnic Type II respiratory failure should be managed with a little more caution and their Sa_{O_2} target should be set between 88% and 92%. Their further management will be discussed in Chapter 30.

MONITORING

All patients demonstrating hypoxia and the need for oxygen therapy should have a full medical history and physical examination. Focus should be placed on pre-existing respiratory or cardiac disease to ensure correct interpretation of the technical data as well as appropriate oxygen targets being set. Pulse oximetry is extremely valuable as a non-invasive measure of arterial oxygenation. Calibrated on normal subjects, their readings must be treated with caution when below 80%, but are accurate above 88%. They may have decreased accuracy in the critically ill, but the mean difference is within 1.3%.[42] Whereas pulse oximetry is an excellent tool for assessing Sa_{O_2} it gives no data regarding pH and/or Pa_{CO_2} as a marker of ventilatory function or the haemoglobin concentration. Thus it cannot be used as a monitor of ventilation, or an absolute assessment of Ca_{O_2}. Thus in scenarios where hypoxaemia is suspected, an arterial blood gas should be performed and interpreted (Chs 18 and 91). Arterial blood gas analysis is the gold standard for assessing respiratory failure. Usually assessed from aspirating blood from a systemic artery, ear-lobe specimens also have utility in assessing Pa_{CO_2} and pH, at less discomfort to the patient. They are, however, less accurate and less precise at lower oxygen tensions.[43,44] An algorithm for the introduction and monitoring of oxygen therapy in acute hypoxia is summarised in **Figure 28.7**.

HAZARDS OF OXYGEN THERAPY

SUPPLY

Medical oxygen supply is a compressed gas. Pipeline supply to the 'wall' is usually at 4 bars of pressure (3040 mmHg). The cylinder supply when full is 137 bar (104 120 mmHg). As such, there are important risks when using oxygen as explosion is a risk. Direct administration of oxygen at delivery pressures carries a real risk of barotrauma to the airway and alveoli, if not governed by an appropriate pressure-limiting valve (e.g. OHE flow meter).

Oxygen also supports combustion. The possibility of sparks in an oxygen-rich environment must be avoided. Patients must not smoke cigarettes when receiving oxygen therapy, even via nasal cannula. Another example is to ensure that oxygen supplies are removed

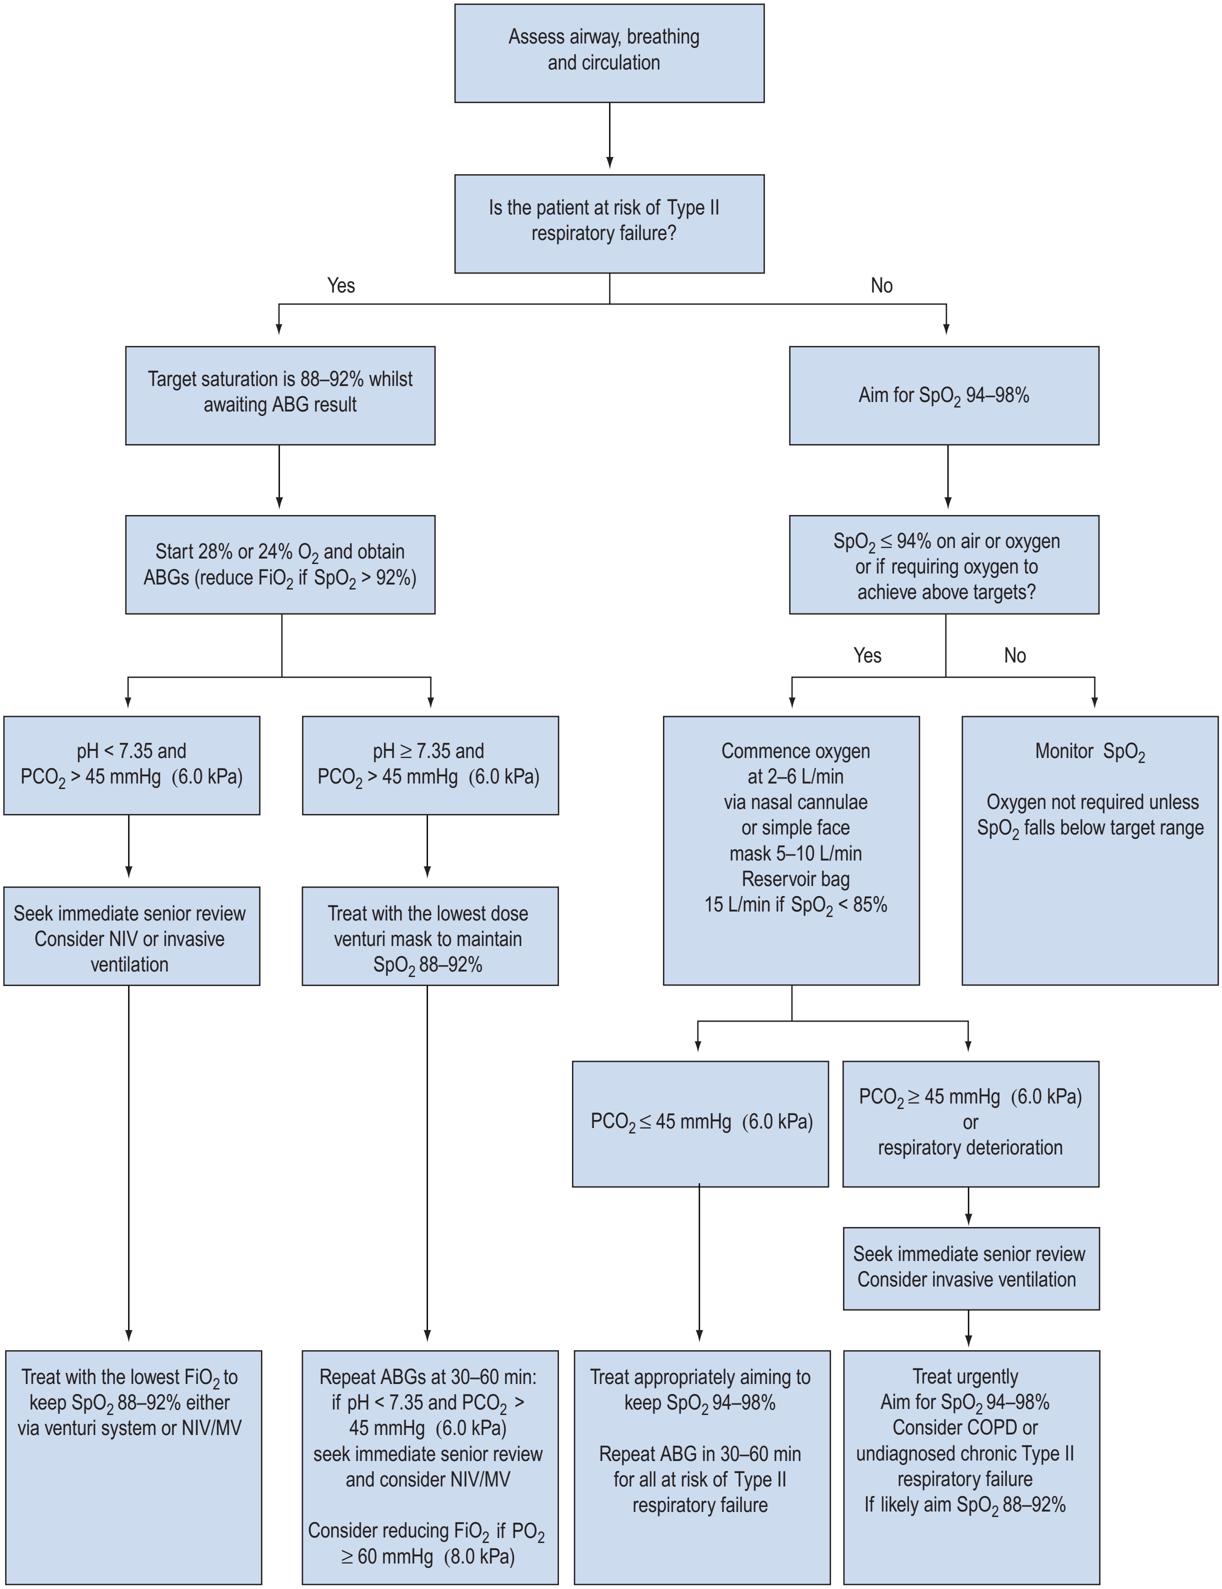

Figure 28.7 Oxygen prescription for acutely hypoxaemic patients in hospital. Any increase in F_{IO_2} must be followed by repeat ABGs in 1 hour or sooner. ABG=arterial blood gas; NIV=non-invasive ventilation; MV=mechanical ventilation. *(Modified from the BTS guidelines 2008.[38])*

or turned off when defibrillating, as a spark can occur in such situations. A recent ICU fire secondary to an oxygen cylinder explosion was reported in the UK.[45]

OXYGEN TOXICITY

Despite being a naturally occurring substance, the use of oxygen in a medical environment should be considered pharmacotherapy. As with all drugs, it has side-effects in overdose. There has been a great interest in the potential toxic effects of oxygen in recent years. As is evident from the above management of oxygen therapy, there needs to be a limit to the concentrations of oxygen used. There is no apparent benefit in hyperoxia except in one or two specific settings. Indeed in the critical care environment studies have shown that a high Pa_{O_2} level within the first 24 hours is an independent risk factor for hospital mortality.[46] This finding remains contentious though, with further studies demonstrating the effect of hypoxia as a predictor of mortality, but no strong effect seen with hyperoxia.[47] Adverse outcomes have also been reported following treatment of post-cardiac-arrest patients with hyperoxia.[48] These findings also have not been reproduced by further studies, but there is still evidence of a U-shaped mortality curve for Pa_{O_2} in this group of patients.[49] What is more certain is the effect of resuscitation with 100% oxygen in neonates. This has been shown to lead to an excess mortality and air is now the recommended gas to be used in the resuscitation of infants.[50]

VASOCONSTRICTION

Oxygen is known to cause constriction of the coronary, cerebral and renal vasculature and, as such, could lead to hypoperfusion of key organ systems – potentially reducing $\dot{D}_{O_2}$ when an increase is desired. This hazard would only be played off against a very moderate increase in Ca_{O_2} assuming all the haemoglobin is saturated. In healthy subjects hyperoxia reduces cerebral blood flow by 11–33%.[51,52] This may be associated with a worse outcome following a mild to moderate cerebrovascular accident.[52] Similarly coronary blood flow is reduced in the presence of hyperoxaemia (8–29% in healthy subjects).[53] This may promote myocardial ischaemia during acute coronary syndromes, possibly increasing myocardial infarction size.[54] This has led UK national guidelines for the management of acute coronary syndromes to stipulate that supplementary oxygen should *not* be given to patients with acute chest pain unless there is evidence of hypoxaemia.[55]

CNS TOXICITY (PAUL BERT EFFECT)

Seen in diving, oxygen delivered at high pressure (>3 atmospheres, ≈300 kPa) can lead to acute central nervous system signs and seizures.

LUNG TOXICITY (LORRIANE SMITH EFFECT)

Exposure to a high Fi_{O_2} results in pulmonary injury. It is known that a progressive reduction in compliance occurs and is associated with interstitial oedema, leading to fibrosis. The mechanism remains unclear, but is believed to involve direct cellular damage to the lung tissue by highly reactive oxygen free radicals. High concentrations of oxygen produce a higher concentration of reactive oxygen species (ROS) that overwhelm the normal scavenging mechanism lining the respiratory tract. This possibly associated with loss of surfactant, and increase in sympathetic activity and airway collapse due to the lack of other non-respiratory gases leads to lung damage. Evidence for this mechanism is supported by the worsening of lung damage seen in paraquat poisoning. Paraquat produces large amounts of ROS, and the administration of supplemental oxygen worsens its effects. Detecting this problem as the sole aetiology for pulmonary pathology can be difficult, especially as the usual indications for oxygen therapy usually imply some form of pulmonary pathology.

It is reasonable that the risk of oxygen-induced pulmonary toxicity is dependent on concentration and duration of exposure. However, the concentration/duration that constitutes ‘likely to cause toxicity’ is not clear. In some subjects long exposure times and high concentrations do not lead to problems. In general, patients should remain below an Fi_{O_2} of 0.5 where possible, and periods above this should be kept to the minimum required.

BRONCHO-PULMONARY DYSPLASIA (BPD)

First described in 1967, this is a form of chronic lung disease associated with neonatal ventilation; its pathophysiology includes the same factors as the adult, but with the additional effect of immaturity.[56] The advent of surfactant in the treatment of respiratory distress of the newborn and the addition of maternal steroid therapy to promote pulmonary development have lowered the incidence and reduced the severity of the disease.

OTHER PULMONARY EFFECTS

Supplemental oxygen also has other more predictable physiological effects within the lungs that may not been seen as truly toxicological, but cause problems in themselves. The greatest is the effect of oxygen on ventilation, especially in those at risk of Type II respiratory failure.

I. *V/Q mismatch:* high concentrations of inspired oxygen will reduce the physiological effects of hypoxic pulmonary vasoconstriction, thus diverting blood through poorly ventilated lung, increasing shunt and reducing Pa_{O_2}. In lungs without chronic disease, this can be compensated for by an increase in ventilation. However, in patients with borderline ventilation, this can lead to increasing Pa_{CO_2} and worsening acidaemia.

II. *Ventilatory drive:* hypoxia below 8 kPa (60 mmHg) leads to an increase in ventilation. Values above

this level have little impact on ventilation. It remains contentious whether this mechanism is important when rises in Pa_{CO_2} are seen in patients with COPD.[57,58]

III. *Haldane effect:* increasing Fi_{O_2} decreases the CO_2 buffering capacity of haemoglobin, thus potentially leading to an increase in Pa_{CO_2} and acidaemia.

IV. *Absorption atelectasis:* in the presence of small-airway obstruction, high alveolar oxygen concentrations result in rapid absorption of gas, causing collapse of the alveoli and reduction in the diffusion surface area. This has been demonstrated even at an Fi_{O_2} of 0.5.[59]

V. *Higher density of oxygen compared with air:* oxygen is more dense than air and thus breathing high concentrations at increased viscosity increases the work of breathing. This effect is probably negligible in patients with normal underlying lungs and neuromuscular function, but can be significant in those with chronic disease.

RETINOPATHY OF PREMATURITY

Previously referred to as retrolental fibroplasia, retinopathy of prematurity (ROP) was first described in 1942. It is a vasoproliferative disorder of the eye affecting premature neonates. Similar to the lungs, the completion of development of the retinal vasculature is late in gestation (32–34 weeks).[60] In the 1950s an epidemic of ROP was described and a causal link to uncontrolled oxygen therapy was made.[61] Improved monitoring of oxygen therapy reduced the incidence of ROP, but was associated with an increase in perinatal mortality secondary to respiratory failure.[62] Subsequently, and despite good oxygen control, ROP continues to occur. This is now most likely due to the increased survival of increasingly premature low-birth-weight infants[63] rather than high Pa_{O_2} alone. This suggests both oxygen- and non-oxygen-related factors. ROP is a biphasic disease where the relatively hyperoxic environment following delivery initially leads to a slowing or even cessation of retinal vascular development of the premature infant. Additional oxygen may further contribute to this problem by affecting the expression of vascular growth factors. The second phase of the disease is a hypoxic-induced neovascularisation, similar to that seen in diabetic retinopathy. This leads to fibrous scarring with risk of retinal detachment. How much oxygen is too much remains contentious and further research is required.[64]

HYPEROXIC AND HYPERBARIC OXYGEN THERAPY

As stated above there are very few indications for increasing the Pa_{O_2} above 'normal', approximately 13 kPa (100 mmHg). Indeed it is likely to be harmful. However, there exist some data to support its use in certain conditions, the majority of which do not involve the critical care physician. These include the treatment of cluster headache, reduction in oxidative stress in colonic surgery and prevention of desaturation during endoscopy.[65–68] The use of hyperoxia to treat postoperative nausea and vomiting and prevent postoperative wound infections lacks high-quality evidence.[66]

ACUTE CARBON MONOXIDE POISONING

Carbon monoxide poisoning as a condition necessitating hyperoxic therapy attracts particular attention. A common consequence of house fires, it binds to haemoglobin with an affinity 210 times that of oxygen. Its half-life in air is 320 minutes, but this can be reduced to 90 minutes by giving the patient 100% oxygen, or 23 minutes with the addition of 3 atmospheres (≈300 kPa) of hyperbaric therapy. Competitive dissociation of carbon monoxide from the haem-binding site and provision of dissolved oxygen to the tissues is believed to combine to reduce the sequelae of carbon monoxide poisoning, but the mechanisms are likely to be more complex.[69] Some studies have suggested both acute and longer-term benefit,[70,71] but others have been unable to conclude significant improvement.[72,73] Recent investigations have attempted to distinguish those patients more likely to benefit from hyperbaric oxygen therapy. Factors such as increasing age (>35 years), an exposure time of >24 hours, an associated loss of consciousness and carboxyhaemoglobin levels greater than 25% appear to result in an increased incidence of neurological sequelae, and probably benefit from hyperbaric oxygen.[74] Geographical distance to an appropriate centre often has a significant influence on hyperbaric usage in the acute setting, but mobile units and some evidence that late therapy may be of benefit should not necessarily preclude its usage.[75,76]

HYPERBARIC OXYGEN

As alluded to in the treatment of carbon monoxide poisoning, oxygen can be delivered to patients at higher than atmospheric pressure (2–3 atmospheres). This serves to increase the amount of oxygen carried in the plasma, rather than bound to haemoglobin. This follows Henry's law that states: 'At a constant temperature, the amount of a given gas dissolved in a given type and volume of liquid is proportional to the partial pressure of that gas in equilibrium with that liquid.' As the partial pressure of oxygen in the environment rises, so to does the amount of oxygen dissolved in the plasma. Consequently, the contribution of the Pa_{O_2} in the Ca_{O_2} formula (28.2) increases. At rest the metabolic demands of an average person can be met by dissolved oxygen alone when breathing 100% at 3 atmospheres.

Hyperbaric oxygen therapy can be delivered either in a monoplace chamber designed for one individual, or in multiplace chambers for 2–10 people. The chambers encompass the whole body, and gas is piped from source, heated and humidified. The common indications and complications of hyperbaric oxygen therapy are listed in **Boxes 28.3 and 28.4**, respectively.[77,78]

Box 28.3 Recognised indications for hyperbaric oxygen therapy[77,78]

Primary therapy	Adjunctive therapy
Carbon monoxide poisoning	Radiation tissue damage
Air or gas embolism	Crush injuries
Decompression sickness (the 'bends')	Compromised skin flaps or grafts
Osteoradionecrosis	Refractory osteomyelitis
Clostridial myositis and myonecrosis	Intracranial abscess
	Chronic wound healing

Box 28.4 Complications of hyperbaric oxygen therapy

- *barotrauma:* middle ear and sinuses, rupture of the oval or round window, gastrointestinal distension, tooth displacement and pain, gas embolism on decompression
- *oxygen toxicity (as above):* especially a problem in the critically ill who may be on high concentrations for longer periods[78]
- *generalised seizures*: Paul Bert effect
- *visual problems:* acute myopia, cataract formation.

Airway management and acute airway obstruction

Gavin M Joynt and Gordon YS Choi

The primary objective of airway management is to clear or bypass the obstructed airway and protect the lungs from soiling. Acute upper airway obstruction is a life-threatening emergency, resulting from a wide range of pathophysiological processes. Rapid assessment and establishment of a patent airway are vital, often in the absence of a specific diagnosis. As no single airway management modality is universally applicable, the intensive care unit (ICU) physician must be capable of performing a variety of airway management techniques (**Fig. 29.1**).

AIRWAY MANAGEMENT TECHNIQUES

Airway management techniques can be considered non-invasive or invasive, depending on whether instrumentation occurs above or below the glottis, and is surgical or non-surgical (**Table 29.1**). Definitive techniques secure the trachea and provide some protection from macroscopic aspiration and soiling. Although most airway management in ICU is still achieved by bag-and-mask ventilation and direct laryngoscopic tracheal intubation, the use of fibreoptic bronchoscopy and video laryngoscopy is increasingly common, especially in special circumstances. Management of failed intubation and ventilation by various alternative techniques (e.g. laryngeal mask airway (LMA) and cricothyroidotomy) is now well described.[1,2]

The technique of choice will depend on each situation and is a consequence of the interaction of patient factors and the clinician's experience (**Table 29.2**). Other factors include availability of help, levels of training and supervision and accessibility of equipment. A portable storage unit with a wide choice of equipment appropriate for difficult airway management is necessary in the ICU (**Box 29.1**).

NON-INVASIVE TECHNIQUES

BAG-MASK VENTILATION

As with most airway management techniques, mask ventilation is a basic skill that requires time and experience to master. It should be learned using mannikins, simulators and practice in the controlled environment of the operating theatre so that when used in the emergency setting in ICU the skill is well established. The bag may be a self-inflating resuscitator, or one attached to an anaesthetic circuit. Most resuscitators require a reservoir bag in series with the self-inflating bag that ensures a high oxygen concentration can be delivered. The addition of positive end-expiratory pressure (PEEP) may improve arterial oxygenation and overcome airway obstruction due to laryngospasm.

Some considerations when performing mask ventilation include the following:

- *Inadequate ventilation:* the seal of the mask against the face may be inadequate and good hand positioning is essential. Ventilation of edentulous patients may be aided by improving hand position or special masks. Two operators are recommended if a mask face leak is excessive: one to hold the mask and the other to manipulate the bag-mask resuscitator.
- *Hyperventilation:* unnecessary hyperventilation may occasionally cause dynamic pulmonary hyperinflation and cardiovascular compromise.
- *Gastric insufflation:* this increases the risk of vomiting and aspiration. Carefully applied cricoid pressure may prevent gastric gas insufflation.
- *Pulmonary aspiration:* in the emergency situation with a full stomach, mask ventilation with cricoid pressure may be necessary until the airway can be secured. Passage of a nasogastric tube to aspirate gastric contents may be successful, but emptying cannot be guaranteed and vomiting may be induced.

ORO- AND NASOPHARYNGEAL AIRWAYS

In the unconscious patient, functional obstruction may occur because of loss of muscular tone and inspiratory airway narrowing at the soft palate, epiglottis and tongue base. An oropharyngeal airway device may establish an adequate airway for spontaneous or bag-mask ventilation when proper head positioning is insufficient. It is inserted with the concavity facing the palate and then rotated 180° into the proper position as it is advanced. Complications include mucosal trauma, worsening the obstruction by pressing the epiglottis against the laryngeal outlet if the tongue displaces posteriorly, and occasionally laryngospasm. The following sizes (length from flange to tip) are recommended: large adult: 100 mm (Guedel size 5), medium adult: 90 mm (Guedel size 4), and small adult: 80 mm (Guedel size 3).

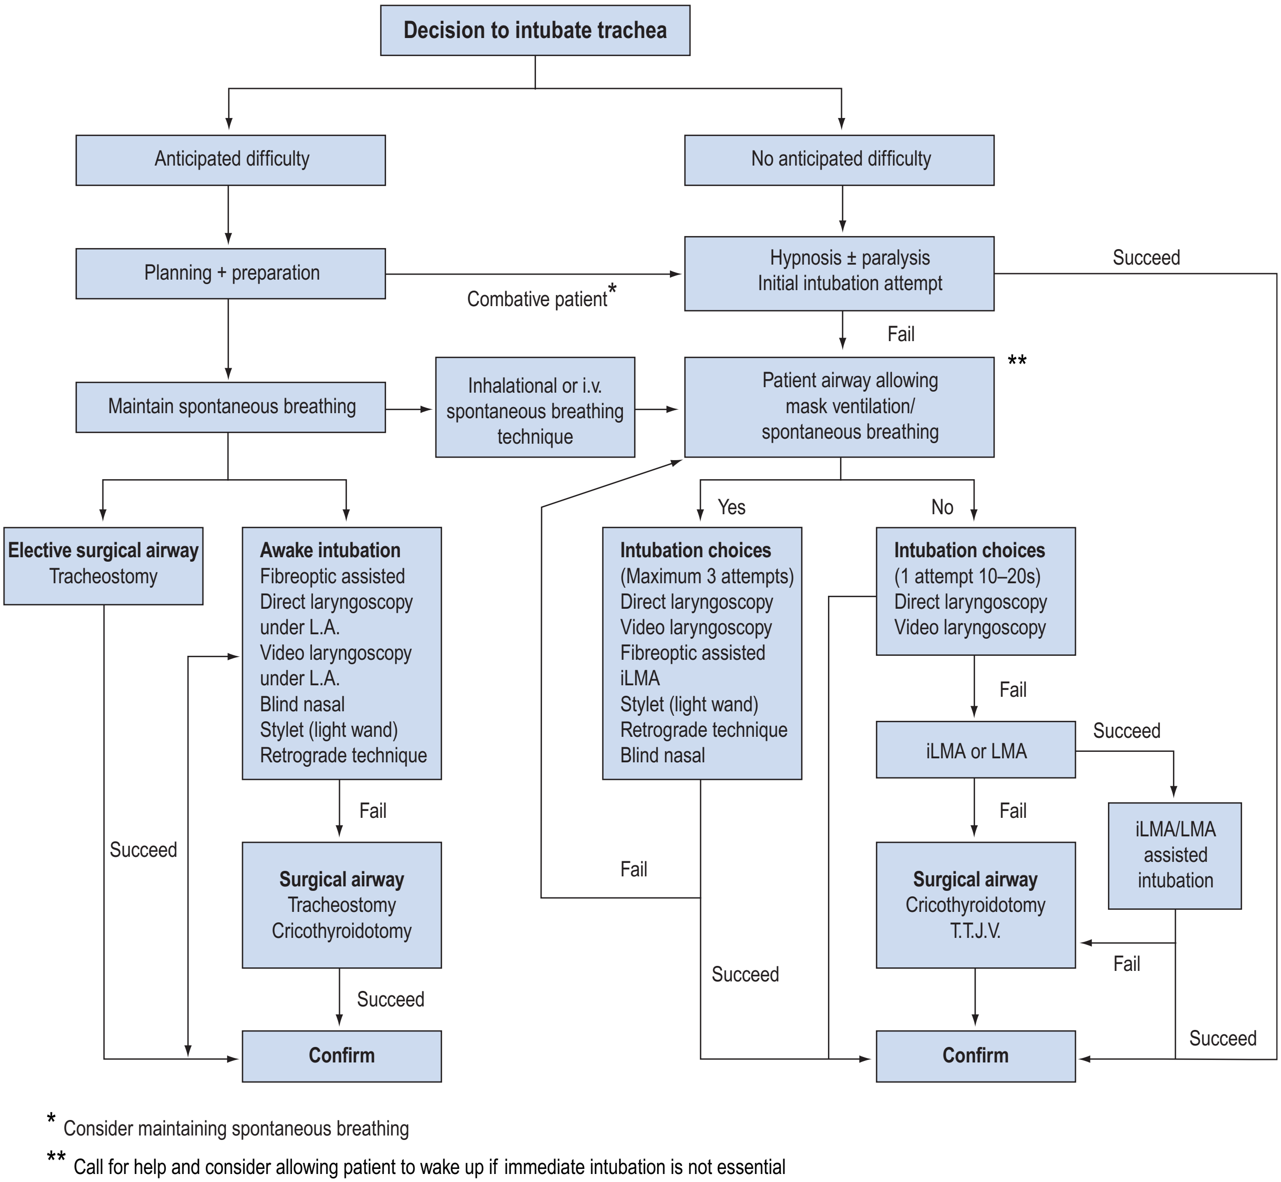

Figure 29.1 Difficult airway algorithm (see text). LA=local anaesthetic; iLMA=intubating laryngeal mask airway; LMA=laryngeal mask airway; TTJV=transtracheal jet ventilation.

A nasopharyngeal airway is a soft rubber or plastic tube inserted into the nostril and advanced along the floor of the nose (in the direction of the occiput). It is better tolerated by semiconscious patients than the oropharyngeal airway. Complications include epistaxis, aspiration and, rarely, laryngospasm and oesophageal placement.

LARYNGEAL MASK AIRWAY (LMA) AND INTUBATING LMA (ILMA)

The LMA is a reusable device that consists of a silicone rubber tube connected to a distal elliptical spoon-shaped mask with an inflatable rim, which is positioned blindly into the pharynx to form a low-pressure seal against the laryngeal inlet.[3] There are a variety of sizes for use in children and adults. LMAs are useful to achieve non-definitive airway patency in many emergency situations (see Fig. 29.1), and can be used to provide limited positive-pressure ventilation.

Once positioned the LMA can be used to guide the passage of stylets, bougies, the bronchoscope or even an endotracheal tube into the trachea.[4] The intubating LMA (FasTrach) is a modification of the LMA with several features to facilitate intubation once the LMA is

placed.[5] There is a guiding ramp and epiglottic elevating bar at the aperture to direct the endotracheal tube to the glottis. It also has an anatomically curved, rigid shaft and handle to allow easy and firm manipulation during placement and when the endotracheal tube is passed.[6]

Table 29.1 Characteristics of airway management techniques

TECHNIQUE	EXPERIENCE REQUIRED	TIME REQUIRED	DEFINITIVE
NON-INVASIVE			
Bag-and-mask	+	Seconds	–
LMA and ILMA	+	1 min	–
Combitube	–	1 min	+
INVASIVE (NON-SURGICAL)			
Endotracheal intubation			
Direct laryngoscopy	+	Variable	+
Bronchoscopic	+	Several minutes	+

LMA=laryngeal mask airway; ILMA =intubating laryngeal mask airway.

The LMA is prepared for insertion by deflating and smoothing out the cuffed rim to be wrinkle-free, and the posterior surface is lubricated with water-soluble jelly. The patient is positioned as for endotracheal intubation, with slight flexion of the neck and extension of the atlanto-occipital joint (sniffing-the-morning-air position). The LMA is inserted with the tip of the cuff continuously applied to the hard palate, and with the right index finger guiding the tube to the back of the tongue until a firm resistance is encountered. The cuff is then inflated with 20–40 mL of air (adult sizes) before attachment of the breathing circuit. The successful use of LMA requires some familiarity with the equipment and technique, and at least simulated exposure is strongly recommended. Contraindications for using the LMA include inability to open the mouth, pharyngeal pathology, airway obstruction at or below the larynx, low pulmonary compliance or high airway resistance. Complications include aspiration, gastric insufflation, partial airway obstruction, coughing, laryngospasm, postextubation stridor and kinking of the shaft of the LMA.

COMBITUBE (OESOPHAGEAL–TRACHEAL DOUBLE-LUMEN AIRWAY)

The oesophageal–tracheal Combitube is a double-lumen tube that is blindly inserted into the oropharynx up to the indicated markings.[7] The oesophageal lumen has a stopper at the distal end and side perforations at the pharyngeal level whereas the tracheal lumen has a hole at the distal end. It has two cuffs, a distal one and a proximal pharyngeal balloon. The patient is ventilated through the oesophageal lumen initially as the Combitube usually enters the oesophagus,[7] with the distal cuff sealing the oesophagus and the proximal balloon sealing the pharynx. Gas exits the perforations and enters the pharynx and larynx. In the event of failure of ventilation, the tracheal lumen is ventilated and the distal cuff seals the trachea.

Endotracheal tube stylets
Gum elastic bougie (Eschmann stylet)
Malleable stylet
Tube changer, hollow tube changer (jet stylet)
Lighted stylet (light wand)
Fibreoptic intubation equipment
Patil endoscopic mask for oral endoscopic intubation
Fibreoptic endoscopes with light source, adult and paediatric-sized
Device for emergency non-surgical airway ventilation
Combitube
Emergency surgical airway access
Percutaneous cricothyroidotomy set
Transtracheal jet ventilation – cannula and high-pressure O_2 source connectors
Regulated central wall O_2 pressure (Sanders-type injector)
Unregulated central wall O_2 pressure
Exhaled carbon dioxide monitor
Capnometer/capnograph
Chemical indicators

Although demonstrated to be useful in the prehospital setting, its role in resuscitation and management of the difficult airway in the ICU environment is yet to be established. Barotrauma, especially oesophageal rupture, has been reported.

INVASIVE TECHNIQUES

ENDOTRACHEAL INTUBATION

Endotracheal intubation remains the 'gold standard' airway management technique, allowing for spontaneous and positive-pressure ventilation, with good macroscopic protection from aspiration. Indications include acute airway obstruction, facilitation of tracheal suctioning, protection of the airway in those without protective reflexes and respiratory failure requiring ventilatory support with high inspired concentrations of oxygen and PEEP.

Prior to proceeding with an intubation attempt, regardless of the technique chosen, pre-oxygenation, as well as preparation and checking of all relevant equipment, is essential. Difficult airway management equipment (see Box 29.1) should also be accessible within a few minutes. Food, vomitus, blood or sputum may obstruct the airway and suction should always be available. Suction apparatus should generate at least 300 mmHg (40 kPa) and 30 L/min. Excessively vigorous suctioning should be avoided as it can cause laryngospasm, vagal stimulation, mucosal injury and bleeding.

Direct laryngoscopy

Although essential for all intensivists, direct laryngoscopy is a difficult skill to master.[8] If multiple intubation attempts are required, the maximum interruption to ventilation should be about 30 seconds. Adequate ventilation and oxygenation must be provided between attempts. Minimum monitoring should consist of continuous-pulse oximetry, electrocardiogram (ECG) and blood pressure. The BURP (Backward, Upward, Rightward Pressure) technique may be helpful to bring the vocal cords into the field of vision. Endotracheal tube size describes the internal diameter and, where possible, 8.0–9.0 mm in adult males and 7.5–8.0 mm in adult females are generally used to facilitate sputum clearance, minimise airway resistance and allow access for fibreoptic bronchoscopy. Special purpose tubes include double-lumen tubes to facilitate lung isolation, spiral imbedded tubes, and laser-resistant tubes.

The route of intubation may be orotracheal or nasotracheal. The orotracheal route is generally recommended because it may be associated with fewer complications.[9] However, nasotracheal intubation allows easier tube fixation and avoids the risk of tube occlusion from biting. It is contraindicated in the presence of fracture of the base of the skull. Other complications include epistaxis, turbinate cartilage and nasal septal damage during insertion.

Stylet guide (introducer)

The 'anterior larynx' can often be more easily intubated if a gum elastic bougie is advanced in the midline and directed anteriorly into the trachea. The endotracheal tube is then advanced over the guide. Clinical signs of correct tracheal placement of the guide include coughing, resistance felt before the guide is fully advanced (usually at 45 cm or less from the lips because of resistance at the carina or bronchus) and a sensation of clicks from the tracheal rings. A number of alternative intubating guides are available, including the hollow

endotracheal tube changer, which can be attached to a side-stream capnometer, or to an oxygen source. The lighted stylet is less commonly used and has a light at the distal end that results in a characteristic midline transillumination appearance when the light enters the larynx.

Rigid indirect fibreoptic instruments

Video-laryngoscopes are newer devices that generate a view of the glottis from near the laryngoscope tip. When used for difficult airway management, they produce similar or better intubation success rates compared with direct laryngoscopy, and reduce cervical spine movement during laryngoscopy.[10] Limitations do exist for each particular device, and both training and operator experience contribute to successful use. Although increasingly available, there is insufficient evidence supporting the routine use of video-laryngoscopy as a replacement for traditional direct laryngoscopy.[10]

Fibreoptic bronchoscopic technique

This technique offers advantages of direct visualisation, immediate diagnosis of upper airway lesions and immobility of the neck during the procedure.[11] It also allows reasonably comfortable intubation of a cooperative, awake patient under local anaesthesia, and use of the sitting position. Experience and skill are necessary, especially for dealing with emergent situations, but success rates >96% are expected.[12] Fibreoptic intubation may also be performed in anaesthetised patients, using a modified facemask with diaphragm for oral intubation. Nasal intubation is usually performed through an endotracheal tube placed in the nasopharynx, with the tip just above the glottis. The fibreoptic bronchoscope tip is guided into the trachea and the tube is advanced over the bronchoscope. Correct placement is visually checked before the scope is removed. In ICU the fibreoptic bronchoscope can be used to improve the safety of airway procedures such as endotracheal tube changes and percutaneous tracheostomy.[13,14] A number of specially designed oral airways are available to assist oral fibreoptic intubation (e.g. the Ovassapian, Williams, or Berman airway). The most common cause of failure is obstructed vision from blood or secretions.

Blind nasal intubation

Blind nasal intubation is sometimes considered in spontaneously breathing patients. Possible indications include inability to open the mouth (e.g. mandibular fracture or temporomandibular joint pathology), and cervical spine and faciomaxillary injury. Contraindications include bleeding disorders, nasal airway obstruction, skull base fracture and pre-existing sinusitis. Operator proficiency is required.

Retrograde intubation technique

A J-tip guidewire (length required in adults approximately 70 cm) is introduced percutaneously through the cricothyroid membrane, and advanced into the retropharynx. The tip is retrieved from the oral cavity, and the wire is used to guide an oral endotracheal tube past the obstruction and into the trachea.[15] The procedure is a relatively simple and safe alternative if other techniques fail or are not possible. Commercial kits are available.

Confirmation of tracheal tube placement

Confirmation of correct intratracheal tube placement is essential. Direct visualisation and measurement of expired CO_2 by capnography are the most reliable methods.[16] Capnography may produce false-positive results with the first few breaths after oesophageal intubation (i.e. detectable PE_{CO_2}), if gastric insufflation from mask ventilation has occurred. A false-negative (decreased PE_{CO_2}, despite correct position) may occur with cardiac arrest and low-cardiac-output states. Position can also be reliably confirmed by the use of self-inflating oesophageal detectors. Other clinical signs, such as auscultation of breath sounds over both sides of the chest and epigastrium, visualisation of condensed water vapour in the tube and chest wall movement are less reliable. The use of capnography is further discussed in Chapter 38.

Complications of endotracheal intubation

These may be classified into those occurring during intubation (e.g. incorrect tube placement, laryngeal trauma, deleterious cardiovascular response to laryngoscopy and intubation, increase in intracranial pressure, hypoxaemia and aspiration), while the tube is in place (e.g. blockage, dislodgment, tube deformation, damage to larynx and complications of mechanical ventilation), and following extubation (e.g. aspiration and postextubation airway obstruction, laryngeal and tracheal stenosis). As few ICU patients can be adequately starved prior to intubation, the use of cricoid pressure, provided it does not obscure the glottic view, is usually required to reduce the risk of aspiration. Hypotension in ICU patients is common immediately following intubation because of drug-induced myocardial depression, decrease in peripheral vascular resistance and sympathetic stimulation, and reduced venous return after positive-pressure ventilation. Fluid administration and the use of vasopressor drugs may be required. Special techniques should be used to minimise side-effects such as cardiovascular responses and increases in intracranial pressure when appropriate.

TRANSTRACHEAL JET VENTILATION (TTJV)

Percutaneous TTJV, using a large-bore intravenous (i.v.) catheter inserted through the cricothyroid membrane, can be used to provide temporary ventilation when other techniques have failed.[17] Ventilation through the cannula with a standard manual resuscitator bag is inadequate, and a jet injector system is necessary. A high-pressure (up to 50 psi or 344 kPa) oxygen source

is required for adequate ventilation through a 14 FG i.v. cannula. Expiratory gases must be able to escape via the glottis. Appropriate chest movements during expiration must be noted. The consequence of expiratory obstruction is severe and potentially fatal barotrauma.

Complications may be caused by insertion of the i.v. cannula (e.g. bleeding and oesophageal perforation), use of high-pressure gases (e.g. hyperinflation, barotrauma), catheter kinking or displacement (the latter causing potentially catastrophic subcutaneous emphysema) and failure to protect the airway (i.e. aspiration).

CRICOTHYROIDOTOMY

Cricothyroidotomy, by surgery or percutaneously, is a reliable, relatively easy way of providing an emergency airway.[18] It is the method of choice if severe or complete upper airway obstruction exists. The simplest, fastest and most proven method uses a horizontal incision through the cricothyroid membrane (with the space held wide open by the scalpel handle or forceps), followed by insertion of a small tracheostomy or endotracheal tube (**Fig. 29.2**). Commercial cricothyroidotomy sets, using the Seldinger technique, are available. A tube with internal diameter of 3.0 mm will allow adequate gas flow for self-inflating bag ventilation provided supplemental oxygen is used. Since the diameter of the cricothyroid space is 9 by 30 mm, tubes of 8.5 mm outer diameter or less should avoid laryngeal and vocal cord damage. Complications such as subglottic stenosis (1.6%), thyroid fracture, haemorrhage and pneumothorax are acceptably low. Cricothyroidotomy is generally contraindicated in complete laryngotracheal disruption and age <12 years.

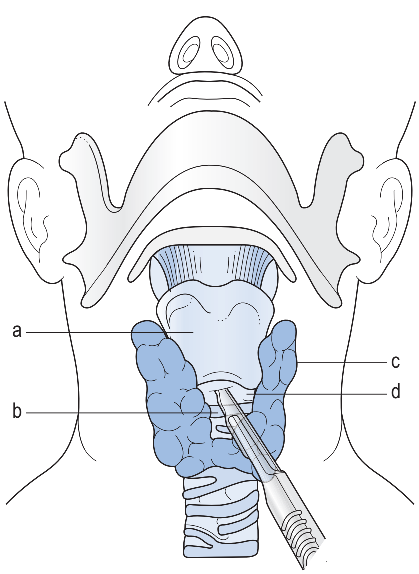

Figure 29.2 Cricothyroidotomy performed with a scalpel: (a) thyroid cartilage; (b) cricoid cartilage; (c) thyroid gland; (d) cricoid membrane, usually easily palpable subcutaneously.

TRACHEOSTOMY

There is little agreement on the indications, best technique or optimal timing of tracheostomy in ICU patients. Suggested indications for tracheostomy include:[19]

- bypass of glottic and supraglottic obstruction
- access for tracheal toilet
- provision of a more comfortable airway for prolonged ventilatory support
- protection of the airways from aspiration.

In uncomplicated patients, percutaneous tracheostomy performed by an intensivist at the bedside is at least as safe as surgical tracheostomy performed in the operating room, and is probably associated with a lower incidence of infectious complications.[20,21] Convenience and cost savings have made percutaneous tracheostomy the procedure of choice in many institutions. Ciaglia's percutaneous technique was described in 1985.[22] After making an adequate skin incision and using blunt dissection with forceps, the endotracheal tube is first withdrawn so that its cuff lies just above the vocal cords. The operator confirms tube position to be above the stoma site by palpation of the trachea. A J-wire is placed in the trachea through a needle inserted through the membrane above or below the second tracheal ring.

Curved dilators can be used to enlarge the stoma. A tracheostomy tube is then inserted into the trachea and the endotracheal tube removed. A modified tapered dilator to avoid the use of multiple dilators is quicker to use, but may cause more tracheal wall injuries and ring fractures. The Griggs technique utilises a Kelly forceps, modified to allow it to be guided by the J-wire, to dilate the tract before insertion of the tracheostomy tube.[23] The speed and safety of the two techniques are similar, although the Griggs technique may cause marginally more bleeding and cannula insertion may be more difficult.[24] Fibreoptic bronchoscopy during percutaneous tracheostomy may help to prevent incorrect guidewire placement and tracheal ring rupture or herniation, but definitive evidence supporting its routine use is lacking.[25]

Minitracheostomy describes the percutaneous insertion of a small 4 mm non-cuffed tracheostomy tube through the cricothyroid membrane or trachea, mainly to facilitate suctioning in patients with poor cough ability. Complications of tracheostomy are listed in **Box 29.2**.

LOCAL ANAESTHESIA

Instrumentation of the upper airway in awake patients requires good local anaesthesia to increase comfort, improve cooperation, attenuate cardiovascular responses and reduce the risk of laryngospasm. Rapid transcricoid injection, 'spray as you go' with a fibreoptic bronchoscope,

Table 29.3 Local anaesthesia of the upper airway in adults

TECHNIQUE	DRUG DOSAGE
NERVE BLOCK	
Internal branch of superior laryngeal nerve	Lidocaine 1–2% (2 mL/side)
Glossopharyngeal nerve	Lidocaine 1–2% (3 mL/side)
TOPICAL ANAESTHESIA OF THE TONGUE AND OROPHARYNX	
Gargle	Lidocaine viscous 4% (5 mL)
Commercial lidocaine spray	Lidocaine 10% (5–10 sprays=50–100 mg)
Nebulised	Lidocaine 4%
Spray as you go	Lidocaine 1–2%
TOPICAL ANAESTHESIA OF THE NASAL MUCOSA	
Cocaine spray or paste	Cocaine 4–5% (0.5–2 mL)
Gel	Lidocaine 2% gel (5 mL)
Commercial lidocaine spray	Lidocaine 10% (10 sprays=100 mg)
Lidocaine laryngeal mask airway+phenylephrine spray	Lidocaine 3%+phenylephrine 0.25% (0.5 mL)
TOPICAL ANAESTHESIA OF GLOTTIS AND TRACHEA	
Spray-as-you-go through bronchoscope	Lidocaine 1–4% (3 mg/kg)
Cricothyroid membrane puncture	Lidocaine 2% (5 mL)
Nebulised	Lidocaine 4% (4 mL)±phenylephrine 1% (1 mL)

Box 29.2 Complications of tracheostomy

Immediate
Procedural complications
- Haemorrhage
- Surgical emphysema, pneumothorax, air embolism
- Cricoid cartilage damage

Misplacement in pretracheal tissues or right main bronchus
Compression of tube lumen by cuff herniation
Occlusion of the tip against the carina or tracheal wall

Delayed
Blockage with secretions
Infection of the tracheostomy site, tracheobronchial tree, and larynx
Pressure on tracheal wall from the tracheostomy tube or cuff
- Mucosal ulceration and perforation
- Deep erosion into the innominate artery
- Tracheo-oesophageal fistula

Late
Granulomata of the trachea
Tracheal and laryngeal stenosis
Persistent sinus at tracheostomy site
Tracheomalacia and tracheal dilatation

or nebulised lidocaine to the nares, posterior pharynx and tongue is effective (Table 29.3).[26] Nerve block techniques may improve analgesia but are not essential. Systemic absorption of topically applied lidocaine (maximum dose 4 mg/kg) is variable, and the clinician should be alert for signs and symptoms of toxicity.

THE DIFFICULT AIRWAY

The difficult airway has been described as one in which a conventionally trained anaesthesiologist experiences difficulty with mask ventilation, tracheal intubation or both. Difficult intubations may be expected in 1–3% of patients presenting for general anaesthesia, and the incidence is likely to be considerably higher in ICU patients.

More than 85% of difficult intubations can be managed successfully by experienced clinicians without resorting to a surgical solution. The experience of the operator is probably the most important factor determining success or failure. Experience implies greater manual skills, better anticipation of problems, use of preprepared strategies, and familiarity with multiple techniques. Thus, training of intensivists must specifically include a variety of airway management strategies and skills.

ASSISTANCE AND ENVIRONMENT

The patient's condition may rapidly deteriorate as a consequence of a poorly managed airway emergency. The most senior help available should be immediately summoned. If the situation allows, the patient should be moved to the best location for emergency airway interventions, usually the operating theatre or ICU, and difficult airway equipment requested (see Box 29.1). A senior assistant can help in gaining i.v. access, administering drugs, setting up equipment and managing the airway. A skilled intensivist or ear, nose and throat surgeon (gowned and standing by) can help to provide a surgical airway or perform rigid bronchoscopy to remove foreign bodies.

ANTICIPATING AND GRADING A DIFFICULT AIRWAY

Intubation difficulty can be anticipated or predicted by the following (although the sensitivity and specificity

of individual features and classifications tend to be low):

1. Anatomical or pathological features of difficult intubation in subjects who otherwise appear normal:
   a. short neck, especially if obese or muscular (a thyromental distance <6 cm)
   b. limited neck and jaw movements (e.g. as a result of trismus, osteoarthritis, ankylosing spondylitis, rheumatoid arthritis or perioral scarring)
   c. protruding teeth, small mouth, long high curved palate or receding lower jaw
   d. space-occupying lesions of the oropharynx and larynx
   e. congenital conditions with any of the above features (e.g. Marfan's syndrome).

2. Mallampatti classification[27] of visualising the oropharyngeal structures (a cooperative sitting patient is required for this assessment, and class >2 predicts possible difficulty):
   a. class 1: visible soft palate, uvula, fauces and pillars
   b. class 2: visible soft palate, uvula and fauces
   c. class 3: visible soft palate and base of uvula
   d. class 4: soft palate is not visible.

3. The degree of difficulty experienced visualising the larynx by direct laryngoscopy should be recorded and is commonly graded by the classification of Cormack and Lehane:[28]
   a. grade I: complete glottis is visible
   b. grade II: anterior glottis is not visible
   c. grade III: epiglottis but not glottis is visible
   d. grade IV: epiglottis is not visible.

FAILED INTUBATION AND VENTILATION ALGORITHMS

A preformulated plan in the event of failed intubation and/or ventilation is essential and a number have been described. The algorithm shown in Figure 29.1 is an example. Effective implementation depends on the appropriate use of the algorithm and airway techniques described above.

If the initial attempt at intubation fails, call for help immediately. Repeated attempts at direct laryngoscopy should be avoided unless a more experienced operator intervenes, or a potentially helpful manoeuvre has been carried out (e.g. significant repositioning, externally applied laryngeal pressure or change of laryngoscope blade). Hypoxia will quickly result if the patient is inadequately ventilated between attempts. In addition, oedema and bleeding caused by repeated attempts may impair both mask ventilation and the use of alternative techniques such as fibreoptic intubation. When indicated to prevent hypoxia a surgical airway should not be delayed (see Figs 29.1 and 29.2).

UPPER AIRWAY OBSTRUCTION

ANATOMY AND PATHOPHYSIOLOGY

The upper airway begins at the nose and mouth, and ends at the carina. Obstruction is likely to occur at sites of anatomical narrowing, such as the hypopharynx at the base of the tongue, and the false and true vocal cords at the laryngeal opening. Sites of airway obstruction are classified as supraglottic (above the true cords), glottic (involving the true vocal cords) or infraglottic (below the true cords and above the carina).

The upper airway can also be divided into intrathoracic and extrathoracic portions, which behave differently during inspiration and expiration. The intrathoracic airway dilates during inspiration because it is 'pulled outwards' by negative intrapleural pressure. Positive intrapleural pressure during expiration causes compression and narrowing. Conversely the compliant extrathoracic airway, unexposed to intrapleural pressure, collapses during inspiration and expands during expiration. Recalling this phenomenon helps the understanding of typical clinical signs, imaging and flow–volume loops.

AETIOLOGY

Acute upper airway obstruction may result from functional or mechanical causes (**Box 29.3**). Functional causes include central nervous system and neuromuscular dysfunction. Mechanical causes may occur within the lumen, in the wall or extrinsic to the airway.

CLINICAL PRESENTATION

The signs of sudden complete upper airway obstruction are characteristic and progress rapidly. The victim cannot breathe, speak or cough, and may hold the throat between the thumb and index finger – the universal choking sign.[29] Agitation, panic and vigorous breathing efforts are rapidly followed by cyanosis. Respiratory efforts diminish as consciousness is lost, and death results within 2–5 minutes if obstruction is not relieved. Lethargy, diminishing respiratory efforts and loss of consciousness are late signs of hypoxaemia and hypercarbia. Bradycardia and hypotension herald impending cardiac arrest.

Signs of partial airway obstruction include voice changes and coughing, progressing to drooling, gagging, choking, noisy respiration and inspiratory stridor. Paradoxical chest wall movements and intercostal and supraclavicular retractions may be marked in severe obstruction. Powerful respiratory efforts may produce dermal ecchymoses and subcutaneous emphysema. Respiratory decompensation may be of rapid onset, and progress to complete obstruction.

SPECIAL EVALUATION OR INVESTIGATIONS

If the patient remains stable, specific diagnostic evaluation may be undertaken, provided advanced airway

Box 29.3 Clinical conditions associated with acute upper airway obstruction

Functional causes
Central nervous system depression
- Head injury, cerebrovascular accident, cardiorespiratory arrest, shock, hypoxia, drug overdose, metabolic encephalopathies

Peripheral nervous system and neuromuscular abnormalities
- Recurrent laryngeal nerve palsy (postoperative, inflammatory or tumour infiltration), obstructive sleep apnoea, laryngospasm, myasthenia gravis, Guillain–Barré polyneuritis, hypocalcaemic vocal cord spasm

Mechanical causes
Foreign body aspiration
- Infections
- Epiglottitis, retropharyngeal cellulitis or abscess, Ludwig's angina, diphtheria and tetanus, bacterial tracheitis, laryngotracheobronchitis

Laryngeal oedema
- Allergic laryngeal oedema, angiotensin-converting enzyme inhibitor associated, hereditary angioedema, acquired C1 esterase deficiency

Haemorrhage and haematoma
- Postoperative, anticoagulation therapy, inherited or acquired coagulation factor deficiency

Trauma
Burns
- Inhalational thermal injury, ingestion of toxic chemical and caustic agents

Neoplasm
- Pharyngeal, laryngeal and tracheobronchial carcinoma, vocal cord polyposis

Congenital
- Vascular rings, laryngeal webs, laryngocele

Miscellaneous
- Cricoarytenoid arthritis, achalasia of the oesophagus, hysterical stridor, myxoedema

management facilities and skilled personnel are immediately available.

LARYNGOSCOPY AND BRONCHOSCOPY

Indirect laryngoscopy in a stable, cooperative patient is useful to diagnose foreign bodies, retropharyngeal or laryngeal masses and other glottic pathology.

Assessment with a flexible fibreoptic bronchoscope or laryngoscope is the evaluation method of choice in ICU patients and enables direct visualisation of upper airway anatomy and function. The procedure can be performed without transporting the patient and risking complete obstruction. It can be applied to an awake, spontaneously breathing patient and, with care, should not worsen the obstruction. Definitive airway control by intubation can usually be achieved. Disadvantages are the need for a skilled operator and a cooperative patient, and a reduced visual field limits effectiveness if blood and secretions are copious.

Direct laryngoscopy enables forceps removal of foreign bodies and high-volume suctioning of blood, vomitus and secretions. Endotracheal intubation can rapidly be achieved under direct vision. A disadvantage is the need for general anaesthesia or good local analgesia (often difficult in the emergency setting). Direct laryngoscopy can be traumatic, and may worsen soft-tissue bleeding and oedema.

RADIOGRAPHIC IMAGING

Patients with potentially unstable airways should not be transported from a 'safe' environment like the emergency room, operating theatre or ICU for radiological investigation until the airway is secure. Anteroposterior and lateral plain neck X-rays may be useful to detect radiopaque foreign bodies. Computed tomography (CT), preferably with three-dimensional postprocessing, may provide detailed diagnostic information and prognostic at initial evaluation in stable patients, or in those in whom the airway has been secured.[30,31] Although magnetic resonance imaging (MRI) has been used to image the upper airway, its use in acute airway obstruction is unproven.

GAS FLOW MEASUREMENT

Flow–volume loop measurement reveals characteristic patterns corresponding to different types and position of pathological lesions (**Fig. 29.3**).[32]

MANAGEMENT

Simplified algorithms to assist the management of partial and complete upper airway obstruction are shown in **Figures 29.4** and **29.5** respectively. Improvisation may be required for certain difficult problems. The chosen technique should be an appropriate one in which the clinician has reasonable skill and experience. Special techniques in patients with suspected cervical spine instability are discussed in Chapter 78.

1. Supplemental oxygen (100%) is immediately administered and adequate help summoned.
2. A choice of equipment for definitive airway control must be available and ready for use (see Box 29.1).
3. In adults i.v. access should be secured.
4. Initiate continuous monitoring of vital signs and pulse oximetry.
5. The risk and benefit of patient transport before securing the airway must be carefully considered.

AIRWAY MANAGEMENT TECHNIQUES IN AIRWAY OBSTRUCTION

THE UNCONSCIOUS PATIENT

If the upper airway is obstructed by the tongue and retropharyngeal tissues in an unconscious patient, airway patency is initially achieved by using standard airway manoeuvres[33] and oropharyngeal and

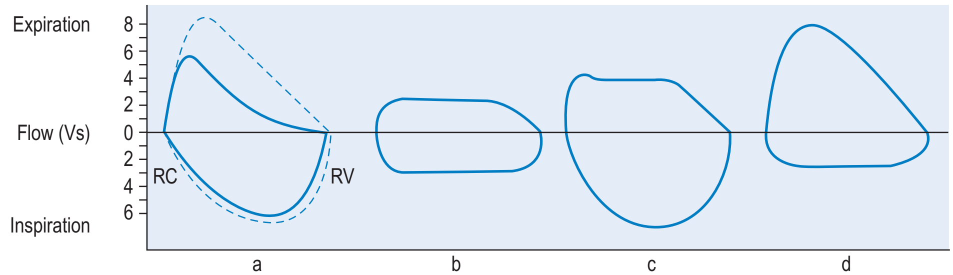

Figure 29.3 Flow–volume loops. Patterns resulting from different pathological lesions: (a) lower airway obstruction (e.g. chronic obstructive pulmonary disease or asthma); (b) fixed, non-variable upper airway obstruction (e.g. fibrous ring in trachea); (c) variable upper airway obstruction, intrathoracic (e.g. tumour in the lower trachea); (d) variable upper airway obstruction, extrathoracic (e.g. vocal cord tumour or paralysis).

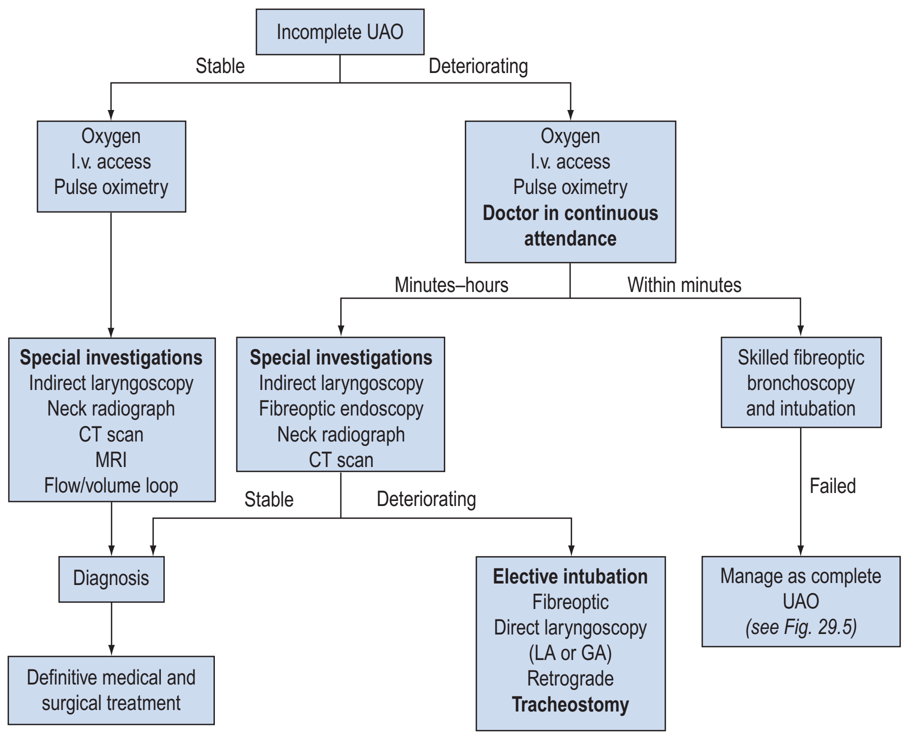

Figure 29.4 Management of partial upper airway obstruction (UAO). i.v.=intravenous; CT=computerised tomography; MRI=magnetic resonance imaging; LA=local anaesthesia; GA=general anaesthesia.

nasopharyngeal airways. Definitive airway control should follow if consciousness does not immediately return.

ENDOTRACHEAL INTUBATION

1. *Direct laryngoscopic intubation* is the method of choice for the unconscious, apnoeic patient as it allows rapid evaluation of any supraglottic problem and immediate airway security. *Video laryngoscopy* is an alternative in experienced hands. Both can also be attempted in an awake patient after careful application of local anaesthesia. Although there is some risk of loss of the airway after local anaesthesia, complete loss of the airway under general anaesthesia is common and may be catastrophic.
2. *Awake fibreoptic intubation* in a spontaneously breathing patient is usually safe, but requires a skilled operator. The procedure will take 2–10 minutes or longer,[34] and urgency of the case must be assessed beforehand with this timeframe in mind. Alternatives should be initiated if the obstruction progresses or if intubation fails after a reasonable time. The following points may assist visualisation in acute upper airway obstruction:

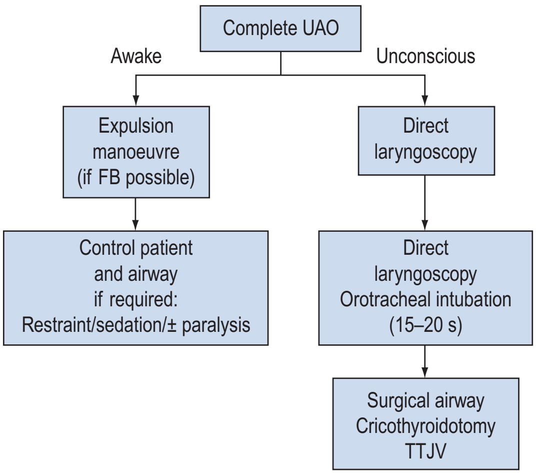

Figure 29.5 Management of complete upper airway obstruction (UAO). Attempts at orotracheal intubation should not take longer than 10–20 seconds. FB=foreign body; TTJV=transtracheal jet ventilation.

- **a.** The procedure should be clearly explained to the patient.
- **b.** Good local anaesthesia and mucosal vasoconstrictors are important (see Table 29.3).
- **c.** If desired, the suction port of the fibrescope can be used to insufflate 100% oxygen or apply local anaesthetic. This also clears the fibrescope tip of secretions. Additional large-bore suction catheters may help. Failure is most commonly due to excessive secretions and bleeding.

3. *Blind nasotracheal intubation* may be considered by experienced operators. Once endotracheal intubation is safely accomplished and confirmed, secure fixation of the endotracheal tube is mandatory. The patient's upper limbs may need to be restrained to avoid self-extubation.

SURGICAL AIRWAYS

A surgical airway is indicated when endotracheal intubation is not possible, or when an unstable cervical spine is threatened by available airway techniques. It is the last line of defence against hypoxia. In airway obstruction, options include the following:

1. *Cricothyroidotomy:* this is the method of choice if severe or complete upper airway obstruction exists.
2. *Percutaneous transtracheal jet ventilation*: the technique must not be used in complete upper airway obstruction because expiratory obstruction can cause severe and potentially fatal barotrauma.
3. *Tracheostomy*: in the emergency setting this is rarely required, although surgical tracheostomy under local anaesthesia may be reasonable under some controlled conditions (see Fig. 29.4).

COMMON CLINICAL CONDITIONS AND THEIR MANAGEMENT

FOREIGN-BODY OBSTRUCTION

Foreign-body obstruction is the most common cause of acute airway obstruction. The elderly, especially those in institutions, are at risk. The use of dentures, alcohol and depressant drugs increases risk. Fatal food asphyxiation or 'café coronary' should be considered in any acute respiratory arrest where the victim cannot be ventilated.[35]

Those still able to cough or speak clearly should be given the opportunity to expel the foreign body spontaneously. Expulsion of the foreign body can be attempted with the Heimlich manoeuvre.[29] From behind, the rescuer encircles his or her arms around the victim, placing the thumb of one fist between the umbilicus and xiphisternum. The fist is gripped by the other hand, and an inward, upward thrust is applied. Chest thrusts (rescuer's arms should encircle the chest, and a fist placed over midsternum) may be of use in pregnancy and obesity. Unwanted effects, such as vomiting, aspiration, fractured ribs, barotrauma and ruptured organs, have been reported. Extract visible solid material with a finger sweep only in unconscious patients.[33] If these manoeuvres fail, management immediately proceeds as shown in Figures 29.4 and 29.5.

EXTRINSIC AIRWAY COMPRESSION

Extrinsic space-occupying lesions can cause upper airway obstruction. Compression from haematomas may be associated with trauma, neck surgery, central venous catheterisation, anticoagulants and congenital or acquired coagulopathies. Haematomas following surgery should immediately be evacuated by removing skin and tissue sutures. If this fails, an artificial airway must be secured immediately. In patients with coagulation abnormalities, intubation is preferred over a surgical airway. Most haematomas secondary to coagulopathy do not require surgical intervention, and resolve with conservative therapy (i.e. vitamin K and blood component therapy).

Partial airway obstruction caused by retropharyngeal abscess is best managed by drainage under local anaesthesia. Gentle fibreoptic examination and intubation or direct laryngoscopy and intubation may be considered. Risks are related to inadvertent rupture of the abscess, with subsequent flooding of the airway. Ludwig's angina is a mixed infection of the floor of the mouth resulting in an inflammatory mass in the space between the tongue and the muscles and anterior neck fascia. The supraglottic airway is compressed and becomes narrowed.[36] Direct laryngoscopy is difficult, as the tongue cannot be anteriorly displaced. Awake fibreoptic-guided intubation and a surgical airway, along with antibiotic therapy, are management options.

INTRINSIC AIRWAY COMPRESSION

Burn inhalation and ingestion injury

Patients with large burn area (more than 40%), or with severe facial burns or inhalation injury (soot in the nostrils, burns of the tongue and pharynx, stridor or hoarseness) are at risk of developing progressive supraglottic oedema, usually within 24–48 hours. Such patients may require early prophylactic tracheal intubation. Assessment of injury and need for tracheal intubation can best be decided by frequently repeated awake fibreoptic laryngoscopy, together with close clinical observation.[37] Ingestion of hot fluids or corrosive agents can also cause delayed oedema and airway swelling and should be managed similarly.[38]

Adult epiglottitis

Epiglottitis is an uncommon but increasingly recognised infectious disease in adults.[39] It involves the epiglottis and supraglottic larynx, causing swelling with consequent airway obstruction. *Haemophilus influenzae* and *H. parainfluenzae*, *Streptococcus pneumoniae*, haemolytic streptococci and *Staphylococcus aureus* are common causative organisms. Clinical features are sudden onset of sore throat (pain often greater than suggested by clinical findings), muffled voice, dysphagia, stridor, dyspnoea and respiratory distress. Systemic toxaemia is common. Gentle indirect laryngoscopy, fibreoptic laryngoscopy or lateral neck X-ray confirms the diagnosis. Reported mortality in adults ranges from 0% to 7%.[40]

Airway management is controversial.[40,41] Some experts recommend securing a definitive airway on presentation whereas others suggest close observation in ICU. There are, however, reports of sudden obstruction and death with the latter approach.[40] Onset of dyspnoea, dysphonia, stridor, a rapid clinical course and diabetes may predict the need for intubation.[42] Tracheal intubation and tracheostomy are acceptable, but tracheal intubation may result in better long-term outcome.

Prior to securing the airway, patient positioning is important, and changing from a sitting to supine position may induce complete obstruction. In more stable patients, awake fibreoptic intubation is preferable if a skilled operator is available. Endotracheal intubation under general anaesthesia following gaseous induction is often recommended. Obstruction can occur, even when this procedure is undertaken by a skilled anaesthetist in the operating room.[41] A skilled assistant, scrubbed and ready to secure a surgical airway, may prevent disaster. Rapid-sequence induction using muscle relaxants is dangerous and should be avoided. Tracheostomy under local anaesthesia is a safe alternative.

Airway management is followed by antibiotics and supportive care. Cefotaxime 2 g i.v. 6-hourly or ampicillin 1–2 g i.v. 6-hourly *plus* chloramphenicol 50 mg/kg per day are empirical regimens. Patient factors, local bacterial sensitivities and cultures of blood and epiglottal swabs may influence the antibiotic choice. Supportive care includes adequate sedation and tracheobronchial toilet. Abscesses should be surgically drained. There is no good evidence supporting the use of steroids.

Angioedema

Allergic responses involving the upper airway may be localised or part of a systemic anaphylactic reaction. Angioedema is characterised by subepithelial swelling. Angioedema of the lips, supraglottis, glottis and infraglottis may result in airway obstruction. The systemic reaction consists of variable combinations of urticaria, bronchospasm, shock, cardiovascular collapse and abdominal pain. Common causative agents are Hymenoptera stings, shellfish ingestion and drugs.

Treatment consists of immediately ensuring an adequate airway (see Figs 29.4 and 29.5), and administration of oxygen, epinephrine (adrenaline), histamine antagonists and steroids. Close observation in case of relapse for at least 24 hours after severe reactions is necessary. As it is likely to recur, the patient should be followed-up and fully investigated.

Hereditary angioedema is a rare, inherited disorder of the complement system, caused by functionless or low levels of C1 esterase inhibitor.[43] Non-pruritic, usually non-painful angioedema involving skin and subcutaneous tissue occurs in various locations, including the upper airway.[44] Precipitating causes include stress, physical exertion and localised trauma (including dental or maxillofacial surgery and laryngoscopy). Acute attacks do not respond to epinephrine, antihistamines or corticosteroids. Management consists of establishing a secure airway and infusion of C1 esterase inhibitor concentrate (25 U/kg) which has an onset of action of 30–120 minutes.[44,45] If not available, fresh frozen plasma (2–4 units) may be considered.

Stanozolol 2 mg daily or danazol 200 mg/day has been shown to be effective in decreasing frequency and severity of attacks with reduced side-effects.[46] Antifibrinolytic agents (e.g. tranexamic acid) are less effective. Guidelines recommend use of C1-inhibitor concentrate for preoperative prophylaxis or, if this is unavailable, the dose of attenuated androgen should be doubled for 5 days before and 2 days after the procedure. Icatibant acetate, a subcutaneous synthetic peptide blocker of the bradykinin-2 receptor, and ecallantide, a subcutaneous recombinant protein kallikrein antagonist, have both recently become available for the symptomatic treatment of hereditary angioedema.[46] Angiotensin-converting enzyme inhibitor-related angioedema is increasingly seen and is possibly the result of reduced bradykinin metabolism.[47] Treatment focuses on airway support.

Postextubation laryngeal oedema

Laryngeal oedema following extubation occurs in about 20% of adults, but is severe enough to precipitate re-intubation in only 1–5%. The risk of postextubation oedema may be increased by excessive airway

manipulation, traumatic intubation, high cuff pressures and duration of tracheal intubation greater than 36 hours (however, after 1 week the risk appears to decline again). Prophylactic use of corticosteroids (e.g. methylprednisolone initiated 12 hours before planned extubation at 20 mg i.v. 4-hourly with the last dose immediately prior to tube removal) has been shown to reduce the incidence of postextubation laryngeal oedema and subsequent re-intubation.[48] Treatment in adults is conservative, with close observation and humidified oxygen therapy. Nebulised plain epinephrine (1–2 mL 1:1000 solution diluted with 2 mL saline or undiluted 1:1000 solution 4–5 mL) or racemic epinephrine (0.25–0.5 mL 2.25% solution in 2–4 mL saline) have been used. Nebulisation may need to be repeated every 30–60 minutes.

Postobstruction pulmonary oedema

Postobstruction pulmonary oedema, also known as negative-pressure pulmonary oedema, may occur after general anaesthesia (incidence 0.05–0.1%) or after relief of acute upper airway obstruction (incidence 11%).[49] This appears to be related to the markedly decreased intrathoracic pressure caused by forced inspiration against a closed upper airway, resulting in transudation of fluid from pulmonary capillaries to the interstitium. In addition, increased venous return may increase pulmonary blood flow and pressure, further worsening oedema. Hypoxia, the hyperadrenergic stress state, and increased ventricular afterload may also affect capillary hydrostatic pressure, although pulmonary capillary occlusion pressure is often normal. The oedema usually occurs within minutes after the relief of the obstruction, but may be delayed several hours.[50] Management includes the application of continuous positive-airways pressure or positive pressure ventilation with PEEP, maintenance of airway patency, oxygen therapy, diuretics, morphine and fluid restriction.

Acute respiratory failure in chronic obstructive pulmonary disease

Matthew T Naughton and David V Tuxen

The term chronic obstructive pulmonary disease (COPD) is applied to patients with chronic bronchitis and/or emphysema. COPD affects up to 10% of the adult population aged >40 years and is the fourth most common cause of death worldwide.[1,2] It is increasing in prevalence particularly in women,[1,2] and is commonly associated with cardiovascular disease, depression, gastro-oesophageal reflux, osteoporosis and cancer.[3,4] Severity of COPD can be easily assessed objectively by spirometry[5] (**Table 30.1**) and functionally based upon dyspnoea and exercise capacity[6] (**Table 30.2**).

An acute exacerbation of COPD (AECOPD) is defined as 'an event in the natural course of the disease characterised by change in dyspnoea, cough or sputum'.[4] AECOPD is the commonest admission diagnosis in UK general hospitals (~16% of admissions).[4] Patients with an AECOPD have an in-hospital mortality of 3–8%, and a 30-day mortality of 14–26% (compared with 8% for myocardial infarction).[2–4,7–9] Cautious oxygen delivery and non-invasive ventilatory (NIV) support have been the major advances in therapy in the past decade, which have resulted in a reduced need for invasive mechanical ventilation (IMV) and improved survival. The need for either IMV or NIV ventilatory support in AECOPD varies considerably across continents: for example in the UK, IMV and NIV are used in 1% and 11% of admissions respectively,[8] whereas in the USA they are used in 3% and 5% of admissions respectively.[9]

AETIOLOGY

The causes of COPD can be divided into environmental and host factors. Environmental factors include tobacco smoke, air pollution, indoor fumes (e.g. indoor cooking with solid biomass fuel) and poor socioeconomic status. The biggest single factor in over 95% of patients with COPD is tobacco smoking (**Fig. 30.1**). However, only approximately 15% of smokers develop COPD. Marijuana smoking may cause premature and quite advanced bullous emphysema compared with tobacco smokers, owing to extremely hot and toxic inhaled smoke held at peak inspiration for prolonged periods of time.[3] Host factors are the balance between circulating proteases and antiproteases (e.g. α-1 antitrypsin deficiency) and the intake of antioxidant vitamins (A, C, E).[10]

PATHOPHYSIOLOGY

Reduced expiratory air flow in COPD is due to both increased airway resistance and reduced lung elastic recoil. Airway resistance is increased by mucosal oedema and hypertrophy, secretions, bronchospasm, airway tortuosity and air-flow turbulence and loss of lung parenchymal elastic tissues that normally support the small airways. Loss of lung elastic recoil pressure is due both to loss of lung elastin and to loss of alveolar surface tension from alveolar wall destruction.

Reduced lung elastic recoil decreases expiratory air flow by reducing the alveolar pressure driving expiratory air flow and by reducing the intraluminal airway pressure, which normally distends small airways during expiration. Forced expiration increases alveolar driving pressure, but also causes dynamic airway compression resulting in no improvement or sometimes reduction in expiratory air flow. These factors are present in varying proportions, depending on the degree of chronic bronchitis and emphysema and the individual patient.

Air-flow limitation results in prolonged expiration, pulmonary hyperinflation, inspiratory muscle disadvantage, increased work of breathing and the sensation of dyspnoea. All these factors are worsened during an exacerbation of COPD.

Pulmonary hyperinflation has both static and dynamic components. The static component remains at the end of an expiratory period long enough for all expiratory air flow to cease (30–120 s), enabling the lungs and chest wall to reach their static functional residual capacity (FRC). This component of hyperinflation is due to loss of parenchymal elastic recoil, chest wall adaptation[11] and airway closure, which occurs throughout expiration. Dynamic pulmonary hyperinflation is the further increase in hyperinflation due to slow expiratory air flow not allowing completion of expiration before the arrival of the next breath. The extent of dynamic hyperinflation depends on the severity of air-flow obstruction, the amount inspired (tidal volume) and the expiratory time.[12] Chest wall hyperinflation leads to suboptimal muscle length–tension

Table 30.1 Global Initiative for Obstructive Lung Disease (GOLD) criteria for COPD severity based upon spirometry[5]

	FEV_1/FVC (%)	FEV_1 (% PREDICTED)
1	<70	>80
2	<70	50–80
3	<70	30–50
4	<70	<30

Table 30.2 The body mass index, airflow obstruction, dyspnoea and exercise capacity (BODE) index (maximum is 10)[6]*

SCORE	0	1	2	3
FEV_1 (% predicted)	>65	50–64	36–49	<35
Six-minute walk distance	>350	250–350	150–250	<150
Modified MRC dyspnoea score	0–1	2	3	4
Body mass index	>21	<21		

*The 4-year survival rates are 80% for a score of 2, 70% for 3–4, 60% for 5–6 and 20% for scores 7–10.
Modified Medical Research Council (MRC) score is from zero (no dyspnoea) to 4 (extreme dyspnoea upon getting dressed or leaving the house). FEV_1=forced expiratory volume in 1 second.

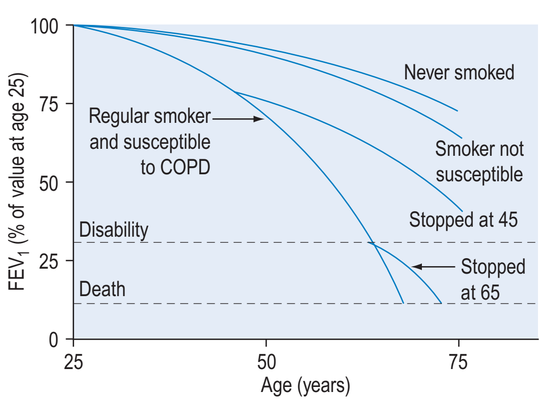

Figure 30.1 Decline in lung function with age in different smoking categories. FEV_1=forced expiratory volume in 1 second; COPD=chronic obstructive pulmonary disease.

relationships and mechanical disadvantage, thereby predisposing patients to respiratory muscle fatigue as the work of breathing increases, particularly if associated with myopathic situations (steroids, electrolyte disturbances).[13,14] Minor reductions in lung function due to infection, mild cardiac failure or atelectasis increase the work of breathing, due to increases in both respiratory impedance and dead space. With acute changes in workload, rapid decompensation with ventilatory failure and acute hypercapnia may occur.

Although chronic hypercapnia, as a consequence of reducing minute ventilation, is a fatigue-sparing mechanism that occurs in some patients, this is usually accompanied by renal compensation with retention of bicarbonate ions to correct the low pH. This has the additional effect of reducing the respiratory distress caused by hypercapnic acidosis. Central respiratory drive may also be impaired, or poorly responsive to physiological triggers – hypoxaemia or hypercapnia – and lead to chronic hypercapnia. This may occur in the setting of sleep (i.e. obstructive sleep apnoea),[11] obesity or drugs (e.g. sedatives, antiepileptics, alcohol).

Hypoxia and vascular wall changes lead to pulmonary vasoconstriction, pulmonary hypertension, cor pulmonale, V/Q mismatching and the development of shunts.

CHRONIC BRONCHITIS OR EMPHYSEMA?

The value of labelling patients as chronic bronchitis or emphysema is uncertain as the two disease processes usually coexist and the principles of management are similar. Five pathophysiological processes may be present to varying degrees in each patient with COPD: (1) inflammatory airway narrowing (bronchiolitis), (2) loss of connective tissues tethering airways, (3) loss of alveoli and capillaries, (4) hyperinflation, and (5) increased pulmonary vascular resistance. Early/mild COPD tends to be dominated by bronchiolitis with a minimal component of emphysema, whereas when COPD becomes severe the reverse is true. However, recognition that COPD is dominated by one of these patterns is helpful with regard to clinical pattern and prognosis.

PRECIPITANTS OF ACUTE RESPIRATORY FAILURE

In approximately 50% of patients there is an infective cause, in 25% heart failure and in the remaining 25% retained secretions, air pollution, coexistent medical problems (e.g. pulmonary embolus, medication compliance or side-effects) or no cause can be identified (**Box 30.1**).[14,15]

INFECTION

The most common bacterial isolates are *Streptococcus pneumoniae* and *Haemophilus influenzae* in 80% of exacerbations. *S. viridans*, *Moraxella* (previously *Branhamella*) *catarrhalis*, *Mycoplasma pneumoniae* and *Pseudomonas aeruginosa* may also be found. Viruses can be isolated in 20–30% of exacerbations and include rhinovirus, influenza and parainfluenza viruses, coronaviruses and occasionally adenovirus, and respiratory syncytial virus. Whether these organisms are pathogens or colonisers is often unclear. Background microbiological agents are identified in 48% of stable COPD, compared

Box 30.1 Precipitants of acute respiratory failure in chronic obstructive pulmonary disease

with 70% during an AECOPD.[16,17] Pneumonia has been estimated to account for 20% of presentations requiring mechanical ventilation.[4]

HEART FAILURE

Left ventricular (LV) systolic failure may result from coexisting ischaemic heart disease, fluid overload, tachyarrhythmias or biventricular failure secondary to cor pulmonale. LV diastolic failure occurs commonly and is precipitated by hypoxaemia, tachycardia, pericardial constraint due to intrinsic positive end-expiratory pressure ($PEEP_i$) or right ventricular (RV) dilation.[11,18,19] Increased work of breathing related to COPD will also increase by up to 10-fold the amount of blood flow to the respiratory pump muscles,[20] thereby causing an increased demand upon the overall cardiac output. In patients with borderline cardiac status, this may precipitate heart failure. The components of RV and LV failure can be accurately distinguished by Doppler echocardiography. Pulmonary congestion can be difficult to diagnose because of the abnormal breath sounds and chest X-ray appearance that are commonly present in COPD. In a recent publication, 51% of patients with acute exacerbation of COPD had echocardiographic evidence of left heart failure (systolic 11%, diastolic 32%, systolic and diastolic 7%).[11] A further study of CT and MR scanning and echocardiography in a large community population (15% of whom had COPD) identified that severity of emphysema on CT scanning indirectly correlated with left ventricular end-diastolic volume, stroke volume and cardiac output.[18] These authors concluded that increasing severity of COPD was associated with worsening cardiac function.

UNCONTROLLED OXYGEN

This may precipitate acute hypercapnia in patients with more severe COPD, due to: (1) shunting blood to low-V/Q lung units and increasing dead space, (2) loss of hypoxic drive, (3) dissociation of CO_2 from Hb molecule (Haldane effect), and (4) anxiolysis and reduction in tachypnoea.[21] Major randomised controlled trials have indicated significant reductions in need for IMV, hospital length of stay and mortality with controlled (or targeted at a specific Sp_{O_2} range – e.g. 88–92%) oxygen therapy compared with uncontrolled oxygen therapy in ambulances,[22] emergency rooms[23] and hospital wards.[8]

DIAGNOSIS AND ASSESSMENT

The clinical examination findings of COPD should be confirmed and severity quantified by spirometry (see Tables 30.1 and 30.2). In mild stable disease (e.g. forced expiratory volume in 1 second (FEV_1) >50% predicted normal), an expiratory wheeze on forced expiration and mild exertional dyspnoea may be the only symptoms.

In moderate-severity COPD (e.g. FEV_1 30–50% predicted normal), modest to severe exertional dyspnoea is associated with clinical signs of hyperinflation (ptosed upper border of liver beyond the 4th intercostal space anteriorly and loss of cardiac percussion) and signs of increased work of breathing (use of accessory muscles and tracheal tug).

In severe stable COPD (e.g. FEV_1<30% predicted normal), marked accessory muscle use is associated with tachypnoea at rest, pursed-lip breathing, hypoxaemia and signs of pulmonary hypertension (RV heave, loud and palpable pulmonary second sound and elevated a-wave in jugular venous pressure (JVP)) and cor pulmonale (elevated JVP, hepatomegaly, ankle swelling).

In severe unstable COPD, there is marked tachypnoea at rest, hypoxaemia and tachycardia, and, in some, signs of hypercapnia (dilated cutaneous veins, blurred vision, headaches, obtunded mentation, and confusion).

Clinical examination may also identify associated medical conditions that might have precipitated the exacerbation such as crackles and bronchial breathing due to infection, crackles and cardiomegaly related to heart failure or mediastinal shift related to a pneumothorax. Acute respiratory failure (ARF) in COPD can present with two distinct clinical patterns[15] (**Table 30.3**), namely relatively thin and normocapnic or obese and hypercapnic.

Basic investigations such as spirometry are very useful for confirming a clinical diagnosis and determining severity of disease. An FEV_1/VC ratio <70% with an FEV_1 of 50–80% predicted normal without a bronchodilator response usually indicates mild COPD. A significant bronchodilator response, which implies asthma, is regarded as a 12% or greater increase and 200 mL increase in either FEV_1 or VC. An FEV_1 30–50% predicted normal indicates moderately severe COPD and FEV_1<30% predicted normal indicates severe COPD.[5]

Flow–volume curves usually demonstrate reduced expiratory flow rates at various lung volumes and the characteristic concave expiratory flow pattern. Lung volumes measured by either helium dilution or plethysmography show elevated total lung capacity, FRC and residual volume. Characteristically, the residual

Table 30.3 Clinical differences between normocapnic and hypercapnic chronic obstructive pulmonary disease

NORMOCAPNIC (Pa_{CO_2} 35–45 MMHG)	HYPERCAPNIC (Pa_{CO_2} > 45 MMHG)
Emphysema > chronic bronchitis	Chronic bronchitis > emphysema
Thin	Obese
Pursed-lip breathing	Central nervous system depression: consider the role of oxygen therapy
Accessory muscle use	Alcohol, sedatives, analgesics
Hyperinflated	Sleep-related hypoventilation
Right heart failure late	Right heart failure early

volume/total lung capacity ratio is >40% in COPD and represents intrathoracic gas trapping. The total lung carbon monoxide (TLCO) uptake is a measurement of alveolar surface area and its reduction approximates the amount of emphysema present (usually <80% predicted normal).

A chest X-ray will commonly show hyperinflated lung fields, as suggested by 10 ribs visible posteriorly, six ribs visible anteriorly or large air space anterior to heart (>⅓ of the length of the sternum), flattened diaphragms (best seen on lateral chest X-ray) and a paucity of lung markings. Pulmonary hypertension is manifested by enlarged proximal and attenuated distal vascular markings and by RV and atrial enlargement. Lung bullae may be evident.

A high-resolution computed tomographic (CT) scan of the chest (1–2 mm slices) can demonstrate characteristic appearance and regional distribution of emphysema. It can also assess any coexistent bronchiectasis, LV failure[24] and pulmonary fibrosis. Such scans are less sensitive than standard chest CT scans (1 cm slice) for detecting pulmonary lesions (e.g. neoplasms). Nuclear ventilation perfusion scans can also provide a characteristic appearance of COPD.

An electrocardiogram (ECG) is commonly normal but may show features of right atrial or RV hypertrophy and RV strain, including P pulmonale, right-axis deviation, dominant R-waves in V1–2, right bundle-branch block, ST depression and T-wave flattening or inversion in V1–3. These changes may be chronic or may develop acutely if there is significant increase in pulmonary vascular resistance during the illness. The ECG may also show coexistent ischaemic heart disease, tachycardia and atrial fibrillation. Occasionally, continuous ECG monitoring is required to identify transient arrhythmias, which may also precipitate acute deterioration. Plasma brain natriuretic peptide (BNP) levels may also assist in the diagnosis of heart failure (elevated BNP) from pulmonary causes (low BNP) in patients under 70 years free of renal impairment.[25]

DIFFERENTIAL DIAGNOSIS

The history of *chronic asthma* is one of long-term dyspnoea, wheeze and cough, usually at night or upon exercise, beginning in childhood with clear-cut precipitating agents (e.g. weather, dust, pets, drugs) and a favourable response to either steroids or inhaled β_2-agonists. Late-onset asthma (>40 years of age) is not uncommon and is often associated with recurrent gastro-oesophageal reflux. In both forms of asthma, TLCO is normal. There is usually a bronchodilator response in the FEV_1 if the patient has unstable asthma. In patients in whom asthma is considered but lung function tests are normal, the FEV_1 response to an inhalational challenge (e.g. methacholine or hypertonic saline) may assist in discriminating asthma from other causes of dyspnoea.

Bronchiolitis obliterans is a condition that presents as a fixed air-flow obstruction following a viral illness, inhalation of toxic fumes, following bone marrow or heart/lung transplantation, or related to drugs (e.g. penicillamine). It generally begins as a cough some weeks after insult and insidious onset of dyspnoea. There is a broad spectrum of radiological appearances from normal to reticulonodular to diffuse nodular. Lung tissue via bronchoscopy or by thoracoscopy is required for diagnosis. Histologically, there is a characteristic chronic bronchiolar inflammation appearance, and if granulation tissue extends into the alveoli it is referred to as bronchiolitis obliterans or organising pneumonia. Removal of the offending agent and instigation of steroids are generally associated with a favourable prognosis.

Bronchiectasis is often associated with fixed mild to moderate air-flow obstruction. A chronic productive cough (daily for 2 consecutive years) is characteristic. Clinical features such as clubbing, localised pulmonary crackles and a characteristic appearance on high-resolution CT, with dilated or plugged small airways at least twice the size of accompanying blood vessel, assist in the diagnosis.

Congestive heart failure (CHF) may be a differential diagnosis of COPD, or simply coexist, as both disorders are common in smokers.[11] Orthopnoea and paroxysmal nocturnal dyspnoea are features that correlate with heart failure severity. A past history of myocardial ischaemia or atrial fibrillation should alert one to the possibility of heart failure. An echocardiogram and high-resolution CT (looking for shift in interstitial oedema with changes in posture from supine to prone)[24] are sensitive markers of CHF.

ASSESSMENT OF RESPIRATORY FAILURE

An acute exacerbation of COPD (AECOPD) is defined as ‘an event in the natural course of the disease characterised by change in dyspnoea, cough or sputum’.[4]

Arterial blood gases are mandatory to assess hypoxia, hypercapnia and acid–base status. Chronic hypercapnia may be recognised by a bicarbonate level

>30 mmol/L and a base excess >4 mmol/L indicating renal compensation. However, other causes of high serum bicarbonate need to be excluded (e.g. diuretic therapy, high-dose steroids or high-volume gastric fluid loss), or chronic hypercapnia may be incorrectly assumed and the severity of COPD overestimated. Renal compensation for chronic hypercapnia will increase the serum bicarbonate by approximately 4 mmol/L for each 10 mmHg (1.33 kPa) of chronic Pa_{CO_2} rise above 40 mmHg (5.3 kPa), in order to return pH to the low-normal range. Irrespective of the COPD patient's usual Pa_{CO_2} level, an acute increase in Pa_{CO_2} leads to a decreased arterial pH. This indicates that compensatory mechanisms are exhausted and there is an increased risk of respiratory collapse. The agreement between arterial and peripheral venous blood gases in terms of pH or Pa_{CO_2} is extremely poor (±0.1 and ±25 mmHg (0.013 and 3.25 kPa) respectively).[26] Thus the use of peripheral venous blood gases to assess respiratory failure should be used with great caution.

MANAGEMENT OF RESPIRATORY FAILURE

NON-VENTILATORY MANAGEMENT

OXYGEN THERAPY

Oxygen given by low-flow intranasal cannulae or 24–35% Venturi mask should be titrated to achieve a saturation (Sp_{O_2}) of 88–92% as these levels will avoid significant increases in Pa_{CO_2} in the majority of COPD patients with ARF. Increases in Pa_{CO_2} are most common in patients with initial Pa_{CO_2}>50 mmHg (6.5 kPa) and pH<7.35.[27] Excessive oxygen therapy is the cause of increased hypercapnia in a third of acidotic AECOPD patients.[8] For this reason, ABGs should be repeated 1 hour following initiation of oxygen therapy, as with NIV, to ensure an optimal direction of improvement in the underlying AECOPD. If the rise in Pa_{CO_2} is excessive (>10 mmHg or 1.33 kPa), then Fi_{O_2} should be reduced, titrating Sp_{O_2} to 2–3% below the previous value, and arterial blood gases should be repeated. If no Pa_{CO_2} rise occurs with oxygen therapy, then a higher Sp_{O_2} may be targeted with repeat ABG.

Inadequate reversal of hypoxia (e.g. Sp_{O_2}<85%) is suggestive of an additional problem such as pneumonia, pulmonary oedema or embolus, or a pneumothorax. Investigation of this should commence and a higher O_2 delivery system should be used (see Ch. 28). Although high levels of O_2 should be avoided, reversal of hypoxia is important and O_2 should not be withheld in the presence of hypercapnia, or withdrawn if it worsens.

BRONCHODILATORS

Bronchodilators are routinely given in all acute exacerbations of COPD because a small reversible component of air-flow obstruction is common, and bronchodilators improve mucociliary clearance of secretions. A large meta-analysis of 22 large randomised controlled long-term trials of ambulatory COPD patients involving anticholinergics and/or β_2-agonists (short- and long-acting) over 3–60 months indicated that anticholinergics are more favourable than placebo in terms of acute exacerbations and hospitalisations.[3,28] There were no favourable advantages with β_2-agonists compared with placebo for acute exacerbations or hospitalisations, and placebo was better than β_2-agonists in terms of respiratory death.[28] There is a cardiovascular risk if given in excessive doses.[29]

Anticholinergic agents, such as ipratropium bromide, have been shown to have a similar or greater bronchodilator action than β-agonists in COPD,[4,5] and also to have fewer side-effects and no tachyphylaxis. Anticholinergic agents should be used routinely in AECOPD. An ipratropium bromide nebule of 0.5 mg in 2 mL should be nebulised initially 2-hourly, then every 4–6 hours. Long-term use of ipratropium bromide has been shown to reduce the incidence of exacerbations[23] and is therefore recommended for chronic use in ambulatory COPD. Long-acting anticholinergics (e.g. tiotropium) offer potential of once-daily dosing.

Nebulised β-agonists are also effective bronchodilators in COPD,[4,5] although they may cause tachycardia, tremor, mild reductions in potassium and Pa_{CO_2} (due to pulmonary vasodilatation) and tachyphylaxis. As in asthma, lactic acidosis may also occur with excessive β-agonists, either nebulised or intravenous. Nebulised β-agonists (e.g. salbutamol, terbutaline or fenoterol) given 2–4-hourly should be used routinely in combination with ipratropium. This combination has been shown to be more effective than either agent alone. Parenteral sympathomimetic agents are not recommended for routine use. In stable patients, long-term use of β-agonists may improve symptoms of dyspnoea, particularly in the subgroup of COPD with an objective bronchodilator response.

STEROIDS

In acute exacerbations of COPD, short-term steroids have been shown to improve air-flow obstruction[30] including those patients requiring mechanical ventilation for COPD.[31] Doses similar to those for acute asthma should be used. Methylprednisolone 0.5 mg/kg, given 6-hourly for 72 hours, was used in the study by Albert et al,[30] demonstrating benefit in patients with an exacerbation of COPD. Current American Thoracic Society guidelines recommend the equivalent to oral prednisolone at 0.5 mg/kg body weight for up to 10 days, then ceasing; however, this will depend upon the response to treatment, and their premorbid use.[5] Steroids should be avoided if the deterioration is clearly due to bacterial pneumonia without bronchospasm.

Longer-term oral steroids in COPD are associated with a substantial increased risk of side-effects (osteoporosis, diabetes, peptic ulcer, myopathy, systemic hypertension, fluid retention, weight gain), and are

therefore not recommended.[5] A small group of patients (15%) may demonstrate a significant bronchodilator response; coexistent asthma is likely in these patients and longer-term high-dose (usually inhaled) steroids may be necessary. In the majority of patients, long-term inhaled steroids do not improve lung function or survival; however, they may improve quality of life and reduce admissions.[5]

ANTIBIOTICS

Antibiotics have an accepted role in the treatment of infection-induced exacerbations of COPD.[4] Amoxicillin is a suitable first-line agent against *Haemophilus influenzae* and *Streptococcus pneumoniae* for outpatient exacerbations. Serious exacerbations requiring hospital admission require newer agents such as ciprofloxacin or a third-generation cephalosporin. Antibiotics for pneumonia are discussed elsewhere in this volume.

AMINOPHYLLINE

Aminophylline is a weak bronchodilator in COPD. It improves diaphragm contractility, stimulates respiratory drive, improves mucociliary transport and right heart function, is anti-inflammatory and is a weak diuretic.[32,33] Some studies have shown no benefit and significant side-effects,[34] whereas others have shown small benefit[35] in stable COPD. For an exacerbation, aminophylline (loading dose 5–6 mg/kg i.v. over 30 minutes, followed by an infusion of 0.5 mg/kg per hour). Serum theophylline levels must be monitored regularly to reduce risk of toxicity.

ANTICOAGULANTS

Subcutaneous heparin (e.g. 5000 units b.d.) is recommended as a prophylactic measure against venous thromboembolism. There is no evidence for warfarinisation in COPD patients with pulmonary hypertension.

ELECTROLYTE CORRECTION

Electrolyte correction is important. Hypophosphataemia,[13] hypomagnesaemia,[36] hypocalcaemia[14] and hypokalaemia may impair respiratory muscle function. Hyponatraemia may occur with inappropriate antidiuretic hormone release or with excess use of diuretics and inappropriate intravenous fluids.

NUTRITION

Nutrition is important, as patients with severe COPD are often undernourished – a subnormal BMI is a risk factor for mortality in COPD. Excessive carbohydrate calories should be avoided as this increases CO_2 production (by >15%) and may worsen respiratory failure. Low-carbohydrate/high-fat combinations are preferred in ARF during spontaneous ventilation.

CHEST PHYSIOTHERAPY

Chest physiotherapy should be initiated and regularly repeated as both a curative and preventive measure. Encouragement of coughing and deep breathing are the two most important factors. 'Bubble positive expiratory pressure (PEP)' is an inexpensive method of assisting sputum clearance in patients with retained secretions or those having difficulty expectorating.

NEBULISED MUCOLYTIC AGENTS

Nebulised mucolytic agents, such as *N*-acetylcysteine, continue to be proposed, although their benefit has never been established in acute exacerbations of COPD. Oral mucolytics have been shown to reduce cough frequency and severity in stable COPD.[37]

NON-INVASIVE VENTILATION (NIV)

NIV, a technique in which ventilatory support is provided via a nasal or facial mask without endotracheal intubation, is now a routine standard of care for AECOPD. When applied well, NIV has the same physiological effect as IMV.[38] Two landmark randomised controlled trials in intensive care wards in 1995[39] and in general medical wards in 2001[40] clearly indicated a role for NIV in hypercapnic AECOPD. Since then, there have been several randomised controlled trials and meta-analyses of NIV in hypercapnic AECOPD which have demonstrated improved respiratory physiology, reduced mortality (up to 12 months), reduced iatrogenic complications, reduced need for intubation and mechanical ventilation and reduced length of stay in hospital.[8,9,41,42] All studies have shown good tolerance of the technique (>80% of patients), with few side-effects, improvements in both oxygenation and Pa_{CO_2} compared with medically treated control patients.

Two important reviews of acute NIV use in AECOPD from the USA and the UK have been recently been published. In the USA between 1998 and 2008, the use of NIV increased (from 1.0 to 4.5% of all admissions) and IMV decreased (from 6.0 to 3.5%) with NIV eclipsing IMV in 2008.[9] Associated with this significant change in pattern of ventilatory support was an overall reduction in mortality in those started on NIV or IMV early.[9] In the UK, during a 3-month snapshot of 232 hospitals during 2008, 11% of all admissions with AECOPD received NIV.[8] Oxygen toxicity was found to occur in a third of hypercapnic AECOPD.[8] In both USA and UK studies, NIV failure with transfer to IMV was associated with greatest mortality (estimated to be ~30 (USA)–40 (UK)%) compared with successfully used NIV (6 (USA)–11 (UK)%) and non-hypercapnic COPD (~3% USA, 5% UK).

The goal of NIV is: (1) to unload respiratory muscles and augment ventilation and oxygenation, reduce CO_2 and correct acidosis until the underlying problem can be reversed; (2) when applied intermittently, to offset the adverse effects of sleep- or position-induced adverse changes to ventilation, increased upper airway resistance and lung volume.

Indications for NIV are a deterioration of COPD with: (1) acute dyspnoea; (2) respiratory rate >28 breaths/min; (3) Pa_{CO_2}>45 mmHg (5.85 kPa) with a

pH<7.35, despite optimal medical treatment and not related to excessive supplemental oxygen. Although these indications are for mild exacerbations, most randomised studies have used these as entry guidelines.[8,41,42] Initial guidelines recommended NIV use to be limited to patients with pH in the range 7.25–7.35; however, recent evidence suggests that NIV is useful even in those patients with lower pH values (to as low as 7.0) and associated more severe hypercapnia (as high as 140 mmHg (18.2 kPa)).[43]

Included in the indications are recently extubated patients in whom NIV has been shown to reduce re-intubation rates significantly.[44,45] Recently NIV has been advocated for use in patients with hypoxic respiratory failure,[46] but success is significantly less in the setting of hypoxaemia and either normocapnia or hypocapnia. NIV may also have a role in some patients where mechanical ventilation is considered inappropriate.

Side-effects of NIV include discomfort, intolerance, skin necrosis, gastric distension and aspiration. Pressure support has been reported as better tolerated than assist/control.[47] End-of-life plans should be considered in all patients with AECOPD, particularly those undergoing NIV, as ~20% of patients will fail to respond or deteriorate. This period of time on NIV can be used to assess resuscitation status.

INVASIVE MECHANICAL VENTILATION

When respiratory failure progresses despite aggressive conservative management, including NIV, invasive mechanical ventilatory (IMV) support may be necessary. The decision to ventilate requires careful consideration in some patients who may have near-end-stage lung disease and whose quality of life may not justify aggressive treatment. This decision requires consideration of the outcome of ARF.

An episode of ARF further decreases survival (**Fig. 30.2**). ARF precipitated only by bronchitis has a better outcome, whereas ARF due to more serious causes such as pneumonia, LV failure and pulmonary embolus has a worse outcome, and studies including all such outcomes have lower survival rates.

If ARF requires IMV, survival decreases further still (see Fig. 30.2). Although only 1[8] to 3.5%[9] of patients with AECOPD require IMV, and 4.5[9] to 11%[8] need NIV, the short-term survival in this more severe subset is still good, with a hospital survival rate in some series as

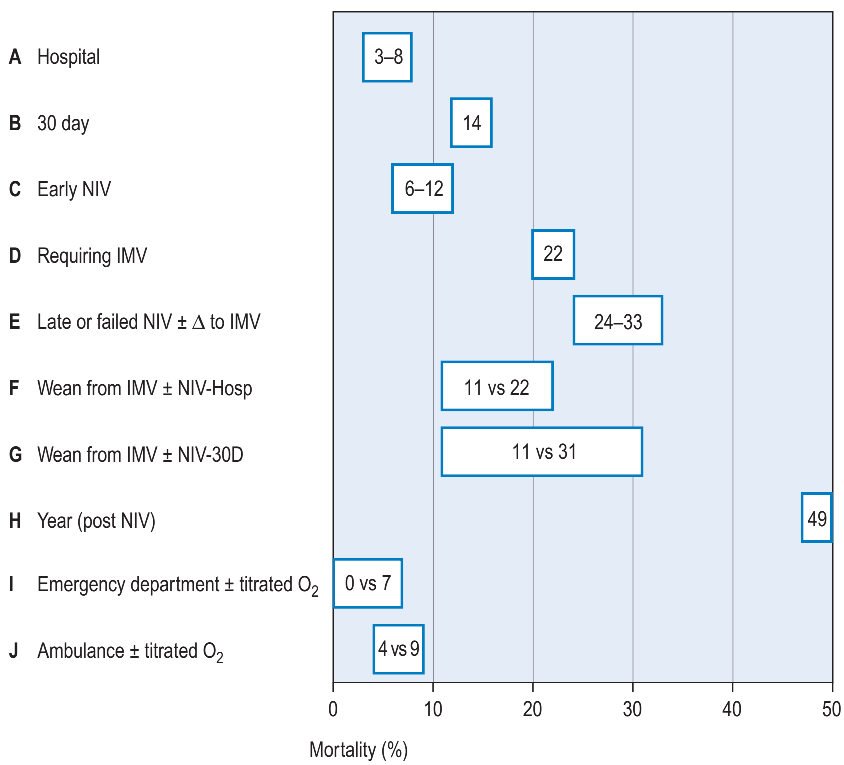

Figure 30.2 Estimated mortality for groups of patients with acute exacerbations of COPD. A and B groups: refer to in-hospital and 30-day mortality;[8,9] C group: refers to early institution of NIV;[8,9] D group: refers to patients requiring IMV;[9] E group: refers to hypercapnic AECOPD patients either failing NIV and needing IMV, or those identified late as requiring NIV;[8,9] F and G groups: weaned from IMV and randomised to either immediate NIV or not (i.e. randomised controlled trial) with in-hospital and 30-day mortality;[44] H group: 1-year mortality post NIV;[7] I and J groups: effect of titrated versus untitrated oxygen at emergency department[23] and ambulance.[22]

high as 90%, but 2- and 3-year survival is significantly lower. The severity of ARF and the severity of underlying COPD based on FEV_1, lifestyle score and dyspnoea score are also predictors of outcome. Lifestyle and dyspnoea categories may be the most useful factors in the decision to withhold IMV. Lifestyle categories 3 (housebound and at least partly dependent) and 4 (bed- or chair-bound) indicate both a poor outcome[48] and quality of life that may not justify aggressive treatment.

Thus IMV may be withheld in end-stage lung disease, when low survival, poor quality of life or permanent ventilator dependence is likely. If end-stage lung disease is suspected but there is insufficient information, then a brief trial of aggressive therapy, including IMV, should be undertaken and subsequently withdrawn if unsuccessful. Despite this, most patients with COPD who present with ARF do not have end-stage disease and, although their immediate problems may be life threatening, their short-term outcome is sufficiently good to justify full active treatment.

INVASIVE MECHANICAL VENTILATION TECHNIQUE

The goals of IMV in COPD are to support ventilation while reversible components improve, to allow respiratory muscle to rest and recover whilst preventing wasting from total inactivity and to minimise dynamic hyperinflation. This is usually best accomplished with low-level ventilatory support. Patients requiring low-level support may be commenced on 8–15 cmH_2O pressure support, with 3–8 cmH_2O PEEP. Patients who are completely exhausted, post arrest, comatose or not tolerating pressure support alone should be commenced or transferred to synchronised intermittent mandatory ventilation mode.

Excessive dynamic hyperinflation must be avoided by using a low-minute ventilation – 115/mL per kg is a guideline[6] – and allowing adequate time for expiration. This should be achieved by the use of a small tidal volume (8 mL/kg) and a ventilator rate <14 breaths/min.[12] Dynamic hyperinflation can be assessed clinically by visualising the expiratory flow–time curve, and by measuring plateau airway pressure (P_{plat}) or $PEEP_i$. P_{plat} should be measured by applying an end-inspiratory pause of 0.5 seconds. This should be applied only following a single breath as it shortens expiratory time and if it is applied to a series of breaths it increases dynamic hyperinflation, resulting in an increased P_{plat} level and increased risk to the patient. If P_{plat} is >25 cmH_2O, there is likely to be excessive dynamic hyperinflation, and the ventilator rate should be reduced. However, P_{plat} may be high without dynamic hyperinflation if chest wall compliance is low. Intrinsic PEEP measured as a prolonged end-expiratory pause more directly assesses dynamic hyperinflation. Provided $PEEP_i$ is accurately measured, it is a useful tool to follow dynamic hyperinflation. In severe air-flow limitation it may be necessary to accept low levels of $PEEP_i$, but as $PEEP_i$ rises above 8–10 cmH_2O further prolongation of expiratory time must be considered. Although still controversial, the use of a high inspiratory flow rate is recommended[12,49] as it results in a shorter inspiratory time and hence a longer expiratory time for a given ventilatory rate. It has been shown to reduce dynamic hyperinflation and alveolar pressure[12] further and to improve gas exchange.[49]

If dynamic hyperinflation is excessive and causing circulatory compromise or risk of barotrauma, then minute ventilation should be decreased, hypercapnic acidosis accepted and spontaneous ventilation, which will only increase dynamic hyperinflation, should be discouraged by sedation. Muscle relaxants should be avoided unless essential. When dynamic hyperinflation is critical during controlled mechanical ventilation, $PEEP_i$ increases pulmonary hyperinflation and should not be applied.[50]

If dynamic hyperinflation is not excessive then spontaneous ventilation should be encouraged to promote ongoing respiratory muscle activity and to minimise wasting. Flow-by, pressure support and low-level CPAP may all reduce the work of spontaneous breathing and promote a better ventilatory pattern. CPAP approximately equal to the level of $PEEP_i$ is most commonly recommended.[51] Care must be taken with all of these supports as each can increase dynamic hyperinflation by a different mechanism, leading to circulatory compromise or risk of barotrauma. Flow-by increases resistance through the expiratory valve, pressure support increases tidal volume and may increase inspiratory time, and CPAP reduces threshold load and makes ventilator triggering easier in patients with PEEPi.

WEANING FROM INVASIVE MECHANICAL VENTILATION

Approximately 6–20% of patients on IMV support fail weaning and place themselves in a high mortality and morbidity group[44,45] (see Ch. 31). Numerous criteria have been proposed to assess the capacity of the patient to wean;[52] however, the predictive value of any of these individual criteria is limited. The simple criterion of patient respiration rate/tidal volume <100 breaths/min per litre had the best predictive value for weaning success, but the advantage of this overly simple clinical assessment during weaning is uncertain. Other indications to extubate COPD patients safely include Fi_{O_2}<40%; Pa_{O_2}/Fi_{O_2}>200, PEEP 5 cmH_2O, cardiovascular stability, afebrile, pH>7.35, Pa_{CO_2}<50 mmHg (6.5 kPa), GCS>10 and, if available to be measured, static compliance >25 mL/cmH_2O.[44] Some patients unable to achieve these criteria may require weaning with Pa_{CO_2} 50–65 mmHg (6.5–8.45 kPa) with a bicarbonate level of >30 mmol/L allowed or encouraged to reduce the work of breathing and achieve a less abnormal pH. Following extubation, weaning can be continued with immediate placement upon NIV, which is associated with reduced re-intubation rates, lower ICU and hospital length of stay and mortality and morbidity.[44,45] Synchronisation of NIV, especially during sleep, is crucial and may require polysomnography.[53]

TRACHEOSTOMY

Tracheostomy may be beneficial in a small group of patients who have failed extubation despite NIV, or who have successfully weaned but are unable to adequately clear secretions, or who have required long-term ventilatory support. After 10 days of endotracheal intubation, the risk of laryngeal trauma and sepsis increases.

A tracheostomy allows long-term ventilatory support, sputum clearance, protection of the upper airway from oral secretions and, off mechanical ventilation, reduced dead space and upper-airway resistance. Compared with naso/orotracheal intubation, tracheostomy is much less intrusive and therefore less sedation is required. Also, it allows direct access to the large airways for the purpose of suctioning and bronchoscopy. However, patients are unable to generate sufficient upper-airway seal to cough, and as such may have ongoing atelectasis until tracheostomy removal and the development of an effective cough. Usually a nasoenteric feeding tube is required. Consider percutaneous endoscopic gastrostomy (PEG) tube feeding if long-term tracheostomy is being considered to avoid nasal trauma and infection and to reduce oesophagitis. Minimal occlusion tracheostomy cuff pressures (usually <20 cmH_2O) should be checked 8-hourly. Adequate humidification and the use of tracheostomies with an inner cannula is recommended to allow for inner tube cleaning or replacement to avoid occlusion by dried secretions.

Consider removing the tracheostomy when:

- the oxygenation requirement is low (e.g. Fi_{O_2} < 40%)
- the patient does not require ventilatory support or requires only intermittent low-level ventilatory support and non-invasive ventilatory support is available
- the patient is cooperative and has a good capacity to cough and can, for example, clear secretions via the tracheostomy tube
- the patient has a low suction frequency requirement (<2–4-hourly).

Before tracheostomy removal, always ensure the patient is able to protect the upper airway from aspiration and can swallow safely and there is an absence of upper-airway obstruction (e.g. no granulation tissue or tracheal stenosis).

POST-INTENSIVE-UNIT CARE

REASSESSMENT OF POTENTIAL PRECIPATING CAUSES

COPD is commonly associated with cardiovascular disease, depression (and social isolation), and occult malignancy – all of which may need further management following an admission. Lung function assessment is crucial post admission and regular follow-up.[3,4]

Assessment for long-term oxygen therapy should be undertaken (Pa_{O_2} < 55 mmHg (7.15 kPa), or <60 mmHg (7.8 kPa) with cor pulmonale) as there are two trials indicating a survival benefit.[54,55] Current smoking is a contraindication to domiciliary oxygen therapy due to the risk of fire. This can be checked by assessing carboxyhaemoglobin values on ABG (>2% suggests smoking) or urinary cotinine levels.

Assessment of underlying obstructive sleep apnoea (COPD and OSA = overlap syndrome) should be considered. Treatment of this combination with CPAP is associated with an improved survival and exacerbation-free survival over a 9.5-year period according to a large, although uncontrolled, Spanish trial.[56] Habitual snoring, witnessed apnoeas, obesity (BMI > 30), large neck size (>45 cm) and crowded oropharynx (Mallampati grade 3–4) provide clues of the possibility of underlying OSA.

DOMICILIARY NOCTURNAL NON-INVASIVE VENTILATORY SUPPORT

In COPD patients with chronic hypercapnia, avoidance of excessive domiciliary oxygen therapy is advised. Whether long-term domiciliary nocturnal NIV is required in this group is less clear. In the two largest studies,[57,58] improved physiology (sleep quality and ABG) were noted overnight without changes in FEV1 and a borderline improvement in survival. Long-term NIV has also been associated with improved ventilation perfusion matching.[29] Patients may benefit from domiciliary NIV if they have the following: (a) confirmed COPD diagnosis with optimal medical treatment and reversal of coexistent medical problems, (b) chronic hypercapnia, (c) at least two admissions with acute acidotic hypercapnia that responded to NIV, (d) demonstration of sleep-related hypoventilation (e.g. total sleep time hypoxic (Sp_{O_2} < 90%) >30% plus a rise in Pa_{CO_2} of >5 mmHg (0.65 kPa)), (e) 1-month trial of domiciliary NIV with objective adherence and improved quality of life and (f) an improvement in physiological markers (e.g. awake Pa_{CO_2} or 6-minute walk distance).

REHABILITATION

Rehabilitation should be considered for all patients with COPD, particularly those following ARF. There are numerous randomised controlled trials showing improvements in exercise physiology, lung function, quality of life and reduced hospitalisation rates.[59] The change in 6-minute walk distance with rehabilitation is a powerful predictor of improved survival and significant patient motivator.[60]

VACCINATION AND ANTIBIOTICS

Two large trials have recently advocated the use of macrolide antibiotics (erythromycin[16] or azithromycin[17]) for stable COPD. Both studies, conducted over a

12-month period, indicated a significant reduction in exacerbations, probably via anti-inflammatory and antibacterial effects. However, this benefit needed to be offset against potential for greater long-term microbiological resistance and side effects such as hearing loss. Vaccination should be considered in all patients with COPD when stable. Annual influenza and 5-yearly pneumococcal vaccination are recommended.[4]

DOMICILIARY OXYGEN

Based upon two studies conducted in the 1970s–80s indicating a mortality benefit,[54,55] supplemental oxygen should be provided to patients with advanced COPD who: (a) are optimally controlled medically, (b) do not smoke, and (c) have Pa_{O_2}<55 mmHg (7.15 kPa) or Pa_{O_2}<60 mmHg (7.8 kPa) with cor pulmonale. Great caution should be undertaken to avoid excessive oxygen at home when stable (aim for overnight oximetry of 88–92%) and during acute exacerbations.[8,22,23]

LUNG TRANSPLANTATION

Lung transplantation is another palliative surgical procedure for patients with advanced disabling COPD who are aged <65 years, are not ventilator dependent, are on less than 10 mg prednisolone/day and are free of significant coexistent disease.[61] The current 1-, 2- and 5-year international survival figures are 75, 66 and 50% respectively. Common complications are systemic hypertension, bronchiolitis obliterans, acute rejection, viral infection with cytomegalovirus and neoplasms.

PROGNOSIS

Patients with sufficiently severe COPD to warrant hospital admission incur an inpatient mortality of 8%, and 90-day mortality of 15% in the UK.[8,9] Predictors of mortality were performance status, age and admission urea, albumin, pH, Pa_{CO_2} and Sp_{O_2} plus the presence of respiratory physicians involved in the care.[62]Although in-hospital mortality for hypercapnic COPD patients may reach 62%,[63] in an Australian report in-hospital mortality for hypercapnic COPD patients treated with NIV was 11% and all deaths were with palliative intent, which followed time to allow for patient and family discussions.[43] In Hong Kong, acute hypercapnic COPD patients have a 12-month re-admission rate of 80% and a 49% 1-year mortality.[7] The body–mass index, air-flow obstruction, dyspnoea and exercise capacity (BODE) index is a 10-point scale made up from the following four variables: (1) body mass index, (2) air-flow obstruction, (3) severity of dyspnoea, and (4) exercise capacity, and has been found to be very useful in predicting survival in ambulatory patients with COPD[6] (see Table 30.2).

Mechanical ventilation

Andrew D Bersten

Mechanical ventilation for acute respiratory failure (ARF) is now routine in the ICU. The 1952 Copenhagen polio epidemic introduced the notion of organised areas (ICU) for the provision of positive-pressure ventilation,[1] which was usually applied through a tracheostomy that had been inserted to allow suction of secretions. However, methods of ventilatory assistance without intubation had proliferated prior to the polio epidemic (both negative-pressure chest wall devices and positive-pressure face-mask devices), and current trends are to an increased use of non-invasive ventilation (NIV) in patients with respiratory failure.[2]

Almost all of the ventilatory modes that are conventionally applied during *intubated* ventilation (IV) can be applied *non-invasively*; however, IV remains the primary mode of respiratory assistance in critically ill patients. There is also an increasing number of patients receiving chronic ventilatory assistance, but, since the majority of these use chronic NIV, this chapter is primarily directed at intubated mechanical ventilation for both ARF and acute-on-chronic respiratory failure.

A PHYSIOLOGICAL APPROACH

During normal spontaneous breathing, contraction of the respiratory muscles overcomes both the elastic recoil and resistance of the respiratory system (lung and chest wall). A fall in regional pleural pressure results in alveolar inflation due to the resultant pressure gradient. Expiration is usually passive, but the expiratory muscles may assist the elastic recoil of the respiratory system.

The work (W) performed by the respiratory muscles (W_{mus}) can be measured from the relationship between pressure (P) and volume (V), and partitioned into elastic (W_{el}) and resistive (W_{res}) work:

$$W_{mus} = W_{el} + W_{res} \tag{31.1}$$

Inertial work is negligible, and usually ignored; furthermore equation 31.1 does not explicitly describe the elastic work required to initiate inspiration when intrinsic PEEP ($PEEP_i$) is present.

Because volume is constant in equation 31.1, it can be simplified to:

$$P_{mus} = P_{el} + P_{res} \tag{31.2}$$

It follows that during positive-pressure ventilatory assistance, where P_{ao} is the ventilatory pressure applied at the airway:

$$P_{ao} + P_{mus} = P_{el} + P_{res} \tag{31.3}$$

and that when the work is solely applied by the ventilator with no respiratory muscle contraction (controlled mechanical ventilation):

$$P_{ao} = P_{el} + P_{res} \tag{31.4}$$

This nomenclature allows physiological discussion of the different ventilatory modes from controlled ventilation to spontaneous, unassisted ventilation, and introduces the equation of motion that is used in the estimation of respiratory mechanics (Ch. 38):

$$P_{ao} = E_{rs} \bullet V + R_{rs} \bullet \dot{V} + P_o \tag{31.5}$$

where E_{rs} is the respiratory system (lung and chest wall) elastance (the inverse of compliance), R_{rs} is the respiratory system resistance, $\dot{V}$ is the gas flow rate, and P_o is the total PEEP (the sum of extrinsic PEEP ($PEEP_e$) and $PEEP_i$). $PEEP_i$ imposes a threshold load – additional elastic work, as inspiratory muscle contraction must occur without $\dot{V}$ until P_{ao} falls below atmospheric pressure (see below, patient–ventilator interaction).

MODES OF VENTILATION

CONTROLLED MECHANICAL VENTILATION (CMV)

The simplest form of positive-pressure breath occurs in a relaxed subject, and the ventilator provides a constant gas flow during inspiration. The volume delivered will depend upon the inspiratory time (T_i), and P_{ao} during inspiration will reflect E_{rs} and R_{rs} (**Fig. 31.1**). Expiration is a passive, and usually exponential, decline in volume to the relaxation volume of the respiratory system, also termed the functional residual capacity (FRC).

CMV is the most basic form of mechanical ventilation; however, it is extremely useful, and still commonly used. Preset minute ventilation is made up from a fixed respiratory rate (f) and tidal volume (V_T). Provided that there are not large variations in alveolar dead space, this maintains a preset alveolar ventilation (V_A) and CO_2 clearance. Consequently, CMV is useful in conditions

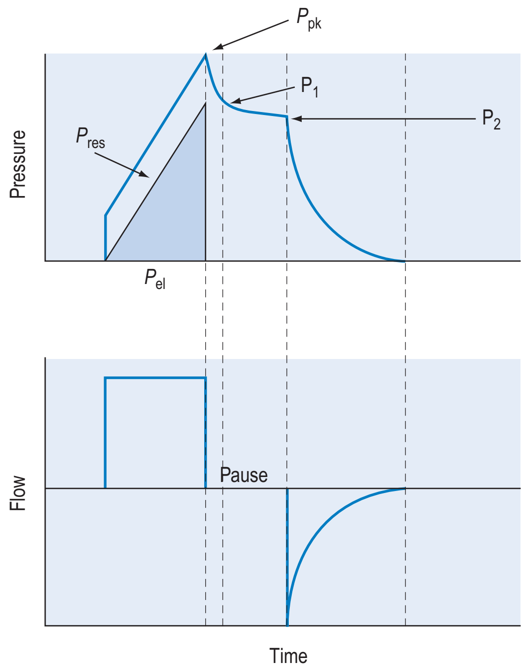

Figure 31.1 Schematic diagram of a volume-controlled breath with constant inspiratory flow. A period of no inspiratory gas flow has been interposed before expiration (pause) to illustrate dissipation of lung resistance as airways resistance (fall from P_{pk} to P_1) and tissue resistance (fall from P_1 to P_2). The inspiratory pressure due to the elastic properties of the respiratory system is illustrated as the filled area (P_{el}), and the lung resistive pressure is labelled as P_{res}. (See text for more detail.)

where there is alveolar hypoventilation (e.g. respiratory muscle weakness), when Pa_{CO_2} needs to be maintained in a fixed range (e.g. raised intracranial pressure) or when the work of breathing must be minimised (e.g. severe cardiorespiratory failure). Because CMV may not match respiratory drive, and spontaneous, supported or assisted breaths are not possible during CMV, sedation and sometimes muscle paralysis may be needed. CMV is usually combined with $PEEP_e$, which can recruit collapsed lung and reduce intrapulmonary shunt. The components are discussed below.

TIDAL VOLUME (V_T)

Larger V_T, typically 12–15 mL/kg, or intermittent recruitment manoeuvres (sighs) prevent progressive atelectasis and intrapulmonary shunt during general anaesthesia.[3] However, this may result in excessive lung stretch, particularly in patients with acute respiratory distress syndrome (ARDS), leading to ventilator-induced lung injury (VILI). For example in ARDS V_T of 6 mL/kg versus 12 mL/kg predicted body weight (i.e. often 4–5 mL/kg versus 9–10 mL/kg true weight) reduced mortality from 40% to 31%.[4] Consequently, lower V_T should be strongly considered during CMV, and other forms of ventilatory assistance, in patients with ARDS; however, greater levels of PEEP are usually required. Whereas the reduction in V_T is particularly applicable to ARDS, excessive lung stretch will be less likely in other patient cohorts that are able to ventilate a greater proportion of the lung (see Ch. 33, Acute Respiratory Distress Syndrome). Intermediate V_T offers more efficient V_A when ventilator support is required for obstructive lung disease as the anatomical dead space fraction is lower.

RESPIRATORY RATE (F)

The desired minute ventilation can be selected from the product of V_T and f. Common CMV rates are 10–20 breaths per minute in adults. Sufficient expiratory time (T_e) must be allowed to minimise dynamic hyperinflation and $PEEP_i$. Although high f (up to 35 breaths per minute) was allowed in the ARDS Network protocol, and the low V_T, low mortality group had a mean f of ~30 breaths per minute,[5] laboratory data suggest a possible additive role of high f in VILI.[5]

INSPIRATORY FLOW PATTERN

The simplest form of CMV uses a constant inspiratory $\dot{V}$ ($\dot{V}_I$) and, in combination with T_i, a preset volume is delivered. This is also called volume-controlled ventilation (VCV); some ventilators use V_T and T_i to set $\dot{V}_I$. Alternative $\dot{V}_I$ patterns that are commonly available with VCV include a ramped descending flow pattern and a sine pattern. When a time preset inspiratory pressure is delivered this is termed pressure-controlled ventilation (PCV).

Although there are no convincing outcome data differentiating these different modes of CMV, PCV is increasingly used when the peak airway pressure (P_{pk}) is high with VCV. However, the alveolar distending pressure, which is usually inferred from the plateau pressure (P_{plat}), is no different provided that T_i and V_T are the same.[6] During PCV, P_{res} is dissipated during inspiration so P_{pk} and P_{plat} are equal, and during VCV P_{res} accounts for the difference between P_{pk} and P_{plat} (**Fig. 31.2**). Similarly, different CMV $\dot{V}_I$ patterns will alter P_{pk} without changing P_{plat} or mean airway pressure (P_{mean}) when T_i and V_T are constant. In ARDS patients, comparing VCV and PCV there was no difference in haemodynamics, oxygenation, recruited lung volume or distribution of regional ventilation.[7] Although PCV may dissipate viscoelastic strain earlier,[7] high $\dot{V}_I$ may cause or exacerbate VILI,[8] which may explain why some animal models have found PCV, which inherently has a high early $\dot{V}_I$, to be injurious compared with VCV.

Pressure-regulated volume control (PRVC) is a form of CMV where the V_T is preset, and achieved at a minimum pressure using a decelerating flow pattern.

INSPIRATORY PAUSE

An end-inspiratory pause allows examination of the decay in P_{pk}, and measurement of P_{plat} (see Ch. 38), and

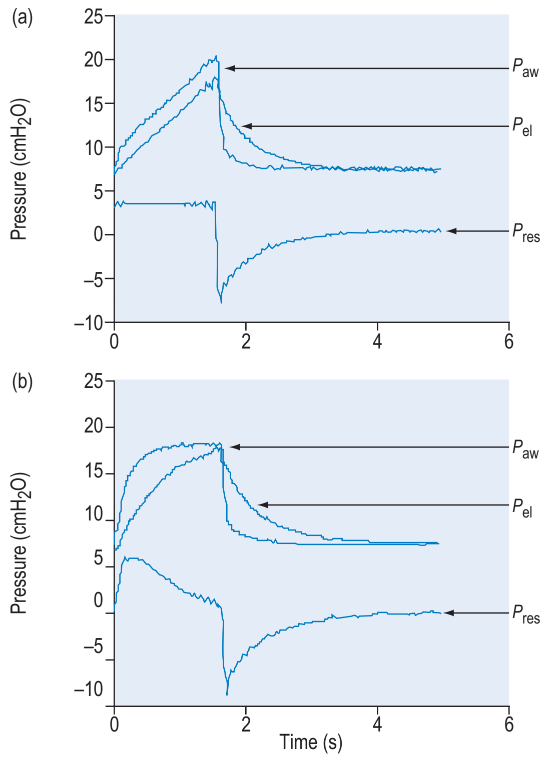

Figure 31.2 Actual pressure–time data from a patient with ARDS ventilated with volume-controlled ventilation (panel a), and then with pressure-controlled ventilation (panel b); tidal volume, I:E ratio and respiratory rate are constant. The airway pressure (P_{aw}, bold line) has been broken down to its components, P_{el} and P_{res} (see Fig. 31.1). Although there is no inspiratory pause, there is marked similarity between panel a and Figure 31.1, with the inspiratory difference between P_{aw} and P_{el} due to a constant P_{res}. In panel b, the decelerating inspiratory flow pattern seen with pressure-controlled ventilation results in dissipation of P_{res} by end inspiration. Consequently, during pressure-controlled ventilation $P_{aw} \approx P_{plat}$ obtained during volume-controlled ventilation. In other words, for the same ventilator settings there is no difference in the elastic distending pressure.

may alter the distribution of ventilation. If T_i and V_T are maintained constant there is no improvement in oxygenation, and a more rapid $\dot{V}_I$ will be needed. Theoretically, during an end-inspiratory pause 32% of the total energy loss within the respiratory system will be dissipated,[9] which may significantly reduce the forces driving expiration, potentially exacerbating gas trapping in patients with severe air-flow limitation.

INSPIRATORY TIME, EXPIRATORY TIME, I:E RATIO

The combination of V_T and inspiratory $\dot{V}$ will determine T_i, which in combination with f sets T_e. A typical T_i is 0.8–1.2 s; with a V_T of 500 mL and inspiratory $\dot{V}$ of 0.5 L/s the T_i is 1.0 seconds. During spontaneous ventilation, the distribution of ventilation at low $\dot{V}$ is determined by regional E, and at high inspiratory $\dot{V}$ by regional R leading to greater ventilation of non-dependent lung. In patients with severe air-flow limitation, high inspiratory flow rates may be used in order to prolong T_e and minimise dynamic hyperinflation.[10]

The I:E ratio is usually set at or below 1:2 to allow an adequate T_e for passive expiration. During inverse ratio ventilation (IRV) the I:E ratio is greater than 1:1. The putative benefits of a prolonged T_i include higher expiratory $\dot{V}$ and improved mucus clearance,[11] and recruitment of long time-constant alveoli, and a short T_e results in gas trapping and PEEP$_i$. Early reports of clinical benefit did not control for PEEP$_i$, and, when total PEEP, f and V_T are constant,[7,8] PCIRV tends to reduce Pa_{CO_2} but does not improve oxygenation, and may have deleterious haemodynamic effects and exaggerate regional overinflation.[7]

POSITIVE END-EXPIRATORY PRESSURE (PEEP)

PEEP is an elevation in the end-expiratory pressure upon which all forms of mechanical ventilation may be imposed. When PEEP is maintained throughout the respiratory cycle in a spontaneously breathing subject, the term constant positive airway pressure (CPAP) is used. The primary role of PEEP is to maintain recruitment of collapsed lung, increase FRC and minimise intrapulmonary shunt. PEEP may also improve oxygenation by redistributing lung water from the alveolus to the interstitium and, although there is no direct effect of PEEP to reduce extravascular lung water, this may occur in patients with left ventricular failure due to a reduction in venous return and left ventricular afterload. Furthermore, inadequate PEEP may contribute to VILI by promoting tidal opening and closing of alveoli. PEEP levels of 5–15 cmH_2O are commonly used, and levels up to 25 cmH_2O may be required in patients with severe ARDS. Although meta-analysis of three large multicentre trials[12] found no benefit of higher PEEP levels in ARDS, mortality was lower in more hypoxaemic patients and there were fewer rescue therapies required, suggesting individual titration may need to be considered.

PEEP titration in ARDS is complex (see Ch. 33, Acute Respiratory Distress Syndrome), and should aim to improve oxygenation and minimise VILI. Since PEEP reduces venous return, cardiac output and O_2 delivery may fall despite an improvement in P_{ao}; indeed this concept has been used to optimise PEEP in ARF.[13] However, in addition to recruitment, increasing PEEP may lead to overinflation of non-dependent alveoli that are already aerated at end expiration.[14,15] Patients with focal ARDS are a particular risk group as recruitment is limited; VILI can be minimised when PEEP is reduced below standard levels.[16] In general, overinflation and VILI are less likely if alveolar distending pressure is kept <30–35 cmH_2O, or the change in driving pressure is <2 cmH_2O when V_T is constant.[17]

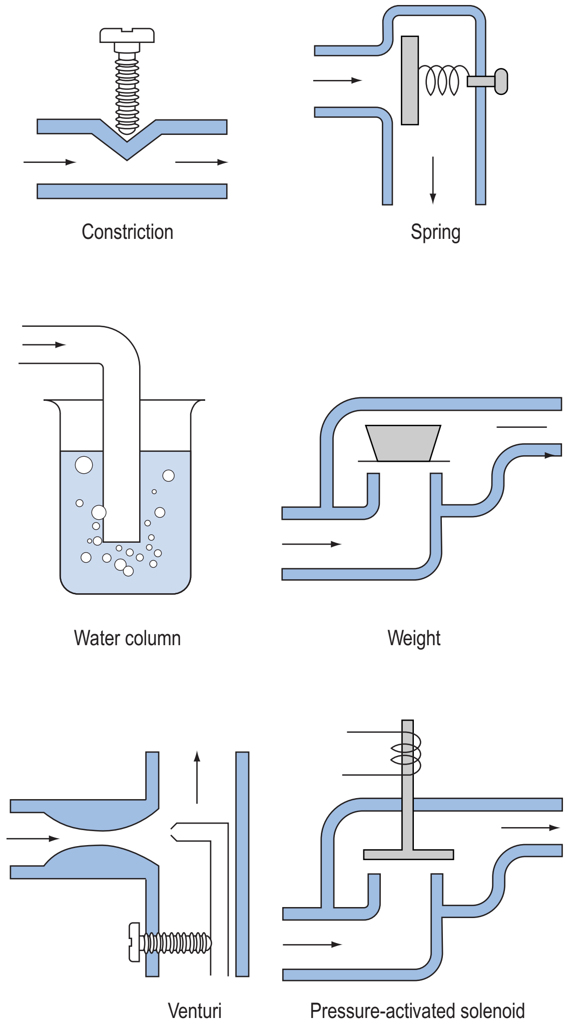

Figure 31.3 Positive end-expiratory pressure values.

$PEEP_e$ is applied by placing a resistance in the expiratory circuit (**Fig. 31.3**), with most ventilators using a solenoid valve. Independent of the technique, a threshold resistor is preferred since it offers minimal resistance to flow once its opening P is reached. This will minimise expiratory work, and avoid barotrauma during coughing or straining.

$PEEP_i$ is an elevation in the static recoil pressure of the respiratory system above $PEEP_e$ at end expiration. $PEEP_i$ arises due to an inadequate T_e, usually in the setting of severe air-flow obstruction. However, it may be a desired end-point during IRV. The sum of $PEEP_e$ and $PEEP_i$ is the total PEEP ($PEEP_{tot}$). The distribution of $PEEP_i$ is likely to be less uniform than an equivalent $PEEP_e$; this may not have the same physiological effects. When patients with severe air-flow obstruction are triggering ventilation, $PEEP_e$ less than $PEEP_i$ may be applied to reduce elastic work (see below, patient–ventilator interaction).

FRACTIONAL INSPIRED OXYGEN CONCENTRATION (Fi_{O_2})

Adequate arterial oxygen saturation is achieved through a combination of minute ventilation, PEEP and Fi_{O_2} adjustment. Even patients with normal respiratory systems usually need an $Fi_{O_2}>0.21$, due to ventilation–perfusion mismatch secondary to positive-pressure ventilation. In patients with ARF it is common to start with an Fi_{O_2} of 1 and titrate down as PEEP and minute ventilation are adjusted. Because high Fi_{O_2}s are damaging to the lung, and nitrogen washout may exacerbate atelectasis, it is reasonable to aim at an $Fi_{O_2} \leq 0.6$.

SIGH

Many ventilators have the ability to intermittently deliver a breath at least twice V_T. Sighs may reduce atelectasis, in part, through release of pulmonary surfactant,[18] resulting in recruitment and improved oxygenation in ARDS.[19] However, if sighs or recruitment manoeuvres are used, care must be taken to avoid recurrent excessive lung stretch.

ASSIST-CONTROL VENTILATION (ACV)

During ACV, in addition to the set f, patient effort can trigger a standard CMV breath (**Fig. 31.4**). This allows greater patient comfort, and V_T is controlled at a safe level; however, there may be little reduction in respiratory work compared to an unassisted breath at low $\dot{V}_I$, because the respiratory muscles continue to contract through much of the breath.[20] The equivalent PCV breath is termed pressure assist-control ventilation (PACV). Differences between triggering modes will be discussed below (patient–ventilator interaction).

INTERMITTENT MANDATORY VENTILATION (IMV), SYNCHRONISED IMV (SIMV)

IMV was introduced over 20 years ago to aid weaning from CMV by allowing the patient to take 'unimpeded' breaths while still receiving a background of controlled breaths. Proposed advantages include a reduction in sedation, lower mean intrathoracic pressure with less barotrauma and adverse haemodynamic consequences, improved intrapulmonary gas distribution, continued use of respiratory muscles and faster weaning. During SIMV T_i is partitioned into patient-initiated and true spontaneous breaths to avoid breath stacking. However, during spontaneous breaths the work of breathing imposed by the endotracheal tube, circuit and ventilator must be overcome.[21] In weaning studies comparing SIMV with T-piece trials and pressure support ventilation (PSV), SIMV is the slowest.[22] Many clinicians add PSV during gradual reduction in respiratory rate with SIMV to overcome the added

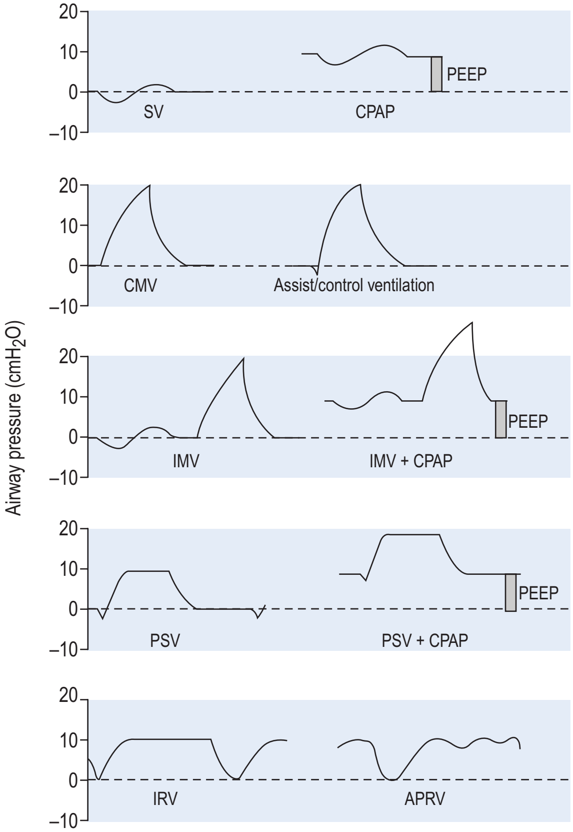

Figure 31.4 Schematic representation of airway pressure versus time for a variety of forms of ventilatory assistance. SV=spontaneous ventilation; CPAP=continuous positive airway pressure; PEEP=positive end-expiratory pressure; CMV=controlled mechanical ventilation; IMV=intermittent mandatory ventilation; PSV=pressure support ventilation; IRV=inverse-ratio ventilation; APRV=airway pressure release ventilation.

respiratory work imposed by the circuit and endotracheal tube; however, this approach has not been formally compared with other weaning techniques, and upper airway oedema following extubation increases extubated W_{res} similar to that imposed by the endotracheal tube prior to extubation.[23]

PRESSURE SUPPORT VENTILATION (PSV)

During PSV, each patient-triggered breath is supported by gas flow to achieve a preset pressure, usually designated to be above the $PEEP_e$. This can be explained by referring to the equation of motion where:

$$P_{mus} + P_{ao} = E_{rs} \bullet V + R_{rs} \bullet \dot{V} + P_o \qquad (31.6)$$

During PSV, P_{ao} is the targeted variable by the ventilator, which leads to a significant and important reduction in P_{mus} and work of breathing.[24] The detection of neural expiration varies between ventilators, but commonly relies upon a fall in the inspiratory $\dot{V}$ to either 25% of the initial flow rate or to less than 5 L/min; some ventilators allow titration of the percentage reduction in initial flow to allow improved patient–ventilator synchrony. PSV may also be titrated to offset the work imposed by the circuit and endotracheal tube. The absolute level required to offset this will vary with endotracheal tube size and inspiratory $\dot{V}$,[25] but is commonly 5–10 cmH_2O.[26] PSV can be used during weaning, or as a form of variable ventilatory support with pressures of 15–20 cmH_2O commonly used. Disadvantages include variable V_T, and hence minute ventilation, the potential to deliver an excessive V_T (common in patients recovering from ARDS) and patient–ventilator asynchrony, which is common with high levels of PSV (see below).

Volume-assured pressure support (VAPS) is a mode of adaptive PSV where breath-to-breath logic achieves a preset V_T.

PROPORTIONAL ASSIST VENTILATION (PAV)

PAV is a form of partial ventilatory support where inspiratory P is applied in proportion to patient effort. Because this allows the breathing pattern and minute ventilation to be matched to patient effort, it is only suitable if respiratory drive is normal or elevated. In concept this should optimise the patient–ventilator interaction; however, the prescription of PAV requires a greater level of physiological understanding than similar forms of partial ventilatory support such as PSV, since there is no target P, V, or $\dot{V}$. PAV is usually prescribed using volume assist (VA) and flow assist (FA), with V and $\dot{V}$ measured continuously. VA generates greater P as V increases leading to elastic unloading, and FA generates greater P as $\dot{V}$ increases leading to resistive unloading. Not surprisingly the units of VA are cmH_2O/L (i.e. an elastance term) and those for FA are $cmH_2O/L/s$ (i.e. a resistance term). This can be illustrated by referring to equation 31.6:

$$P_{mus} + P_{ao} = E_{rs} \bullet V + R_{rs} \bullet \dot{V} + P_o$$

where P_{ao} is determined by PAV, where PAV=VA+FA, so:

$$P_{mus} + \mathrm{VA} \bullet V + \mathrm{FA} \bullet \dot{V} = Ers \bullet V + R_{rs} \bullet \dot{V} + P_o \qquad (31.7)$$

consequently $$P_{mus} = (E_{rs} - \mathrm{VA}) \bullet V + (R_{rs} - \mathrm{FA}) \bullet \dot{V} + P_o \qquad (31.8)$$

If E_{rs} and R_{rs} are known, PAV can, at least in principle, be targeted to reduce a specified proportion of either, or both, elastic and resistive respiratory work. For example, when VA and FA are adjusted to counterbalance E_{rs} and R_{rs} so as to achieve normal values, minute ventilation increases, and respiratory drive and work decrease; if $PEEP_i$ is present, work can be further reduce by applying $PEEP_e$.[27] Respiratory mechanics are relatively hard to estimate in spontaneously breathing

patients, although they are now offered on some ventilators their accuracy has been questioned,[28] which may reduce the validity of adjusting PAV according to estimated load (PAV+). Consequently, PAV is often titrated to patient comfort. Despite a growing body of data demonstrating reduced work of breathing, and improved patient–ventilator synchrony with PAV, it is a more difficult technique to use, and definitive studies showing a clinically important outcome difference are awaited.

NEURALLY ADJUSTED VENTILATORY ASSISTANCE (NAVA)

During NAVA a modified nasogastric tube is used to record diaphragmatic electrical activity, which is used to control the assisting level of inspiratory pressure. This short-circuits trigger and feedback functions with improved patient–ventilator interaction, less asynchrony and less overassistance compared with PSV.[29] NAVA may also improve oxygenation, perhaps by allowing more variable V_T consistent with the concept of biological variability. Although NAVA is available on some commercial ventilators its use is limited, and there are no data showing a clinically important benefit.

BILEVEL VENTILATION

Also described as biphasic positive airway pressure (BIPAP), this is a ventilatory mode where two levels of airway pressure are provided. Cycling between these two levels of airway pressure may be time cycled or triggered by ventilatory effort, in which case inspiratory positive airway pressure (IPAP) and expiratory positive airway pressure (EPAP) are set; however, this is no different to equivalent support with PSV and PEEP. Patient-triggered bilevel ventilation is most commonly used during NIV.

AIRWAY PRESSURE RELEASE VENTILATION (APRV)

During APRV spontaneous breathing is possible in addition to time-triggered and time-cycled biphasic pressure levels (high and low CPAP). Usually the time cycling provides a prolonged T_i aimed at recruiting slow time constant air spaces. Minute ventilation and CO_2 excretion are augmented by brief (1–1.5 s) periodic cycling to the lower level of CPAP. As the augmented V_T is dependent upon elastance of the respiratory system, it will be smaller in patients with 'stiff' respiratory systems. APRV without spontaneous breathing has a similar pressure profile to PCIRV.

APRV offers a number of benefits and is usually applied during IV. The prolonged T_i is usually associated with improved oxygenation at a similar or lower P_{aw} to conventional ventilation. Spontaneous respiratory efforts may: (1) improve matching of ventilation and perfusion due to increased dependent aeration, (2) increase venous return and hence cardiac output or pulmonary blood flow in infants following cardiac surgery[30] and (3) promote reduced sedation. However, randomised clinical trials have not shown improved outcomes,[31] unsupported spontaneous breaths may increase left ventricular afterload and promote ventilator–patient asynchrony and, as slow time constant air spaces are also slow to empty, APRV is contraindicated in COPD and asthma.

HIGH-FREQUENCY VENTILATION (HFV)

HFV encompasses techniques where small V_T (1–3 ml/kg) are delivered at high f (100–600/min). This offers reduced tidal lung stretch and reduced VILI. Hazards include inadequate humidification and gas trapping in patients with severe air-flow limitation. High-frequency jet ventilation (HFJV) utilises dry gas from a high-pressure source delivered into an intratracheal catheter or specifically manufactured endotracheal tube. Although HFJV has been used with improvement in gas exchange in adults with ARDS,[32] high-frequency oscillation (HFO) has received more interest including neonatal, paediatric and adult use.

HFO uses oscillatory flow within the airway to provide active inspiration and expiration at rates of 3–10 Hz. There are a number of putative mechanisms of gas exchange in addition to the more usual bulk flow seen during CMV and SV.[33] Ventilation and V_T are determined by the driving pressure, which controls the reciprocating flow, and by $1/f$. Oxygenation is determined by the mean P_{aw} sometimes in combination with recruitment manoeuvres which influence the volume of recruited lung. Typically the mean P_{aw} is set 5 cmH_2O above the CMV value.[34] Although the mean P_{aw} during HFO is theoretically dissipated with lower alveolar pressures, and this appears to be the case in homogeneous lung injury, damaged regions of the lung with low compliance, and hence short time constants, may be exposed to alveolar pressures approaching mean P_{aw},[35] resulting in regional VILI.

Although oxygenation is improved in both infants and patients with ARDS, definitive outcome data are currently awaited. HFO appears to be equivalent to CMV in preterm infants with similar mortality and chronic lung disease.[36] In ARDS randomised trials have been relatively small and have arguably targeted improved oxygenation rather than lung protection. A meta-analysis of these has suggested reduced mortality with HFO;[28] however, the largest trial included in this analysis administered a V_T of around 10.6 mL/kg predicted body weight in the control CMV group[37] making interpretation difficult. Two large trials with appropriate strategies are currently well under way and should clarify this issue.

LIQUID VENTILATION

Perfluorocarbons have a high solubility for both O_2 and CO_2, and reduce surface tension, somewhat analagous to pulmonary surfactant. Partial liquid ventilation is now the most common method of administration, with perfluorocarbon equal to the functional residual capacity administered via the endotracheal tube. The non-dependent lung is still ventilated, and may have increased blood flow due to compression of the pulmonary circulation in the dependent lung by the perfluorocarbon. Together with the perfluorocarbon-mediated reduction in surface tension, alveoli are recruited and oxygenation improved. However, when PEEP is applied the perfluorocarbon may be pushed distally and overdistend dependent alveoli.

Small clinical studies have reported improved gas exchange and respiratory mechanics after administration of perfluorocarbons;[38] however, a moderately large clinical study (n=311) found that patients receiving conventional ventilation compared with both low- and high-dose perflourocarbons had more ventilator-free days and tended to reduced mortality.[39] Consequently, liquid ventilation cannot be recommended.

INDICATIONS AND OBJECTIVES OF MECHANICAL VENTILATION

Institution of mechanical ventilation is a clinical decision; it can only be supported by parameters such as blood gases or measures of respiratory muscle function. Even then, the decision to choose IV over NIV will be influenced by numerous factors including the indication and its likely course. Often there will be an indication for intubation (**Box 31.1**) and mechanical ventilation; however, if intubation is required to overcome upper airway obstruction no ventilatory assistance may be needed despite the increase in respiratory work imposed by the endotracheal or tracheostomy tube.[18] Once the decision has been made to proceed to ventilatory support the choice of mode should be based on a physiological approach, local expertise, and simplicity.

Patients who are likely to need ventilatory assistance (e.g. acute severe asthma) should be considered for early ICU admission since this will allow faster responses and avoid cardiorespiratory arrest. Specific issues and methods of ventilatory assistance are dealt with in the chapters on ARDS, asthma, COPD and non-invasive ventilation. In patients with traumatic brain injury IV is commonly required to protect the airway and to assist control of ICP, similarly patients with severe pancreatitis or serious abdominal infection may need prolonged IV to maintain an adequate FRC, reduce work of breathing, protect their airway and allow suctioning of secretions.

Box 31.1 Indications and objectives of intubated mechanical ventilation

Endotracheal intubation or tracheostomy
- For airway protection (e.g. coma)
- For suction of secretions
- To assist sedation and neuromuscular paralysis (e.g. to $\downarrow \dot{V}_{O_2}$ $\downarrow$ *respiratory distress*)
- To overcome upper-airway obstruction

Mechanical ventilation
- To manipulate alveolar ventilation (V_A) and Pa_{CO_2} (e.g. reverse respiratory acidosis, $\downarrow$ cerebral blood flow and intracranial pressure)
- To $\uparrow$ Sa_{O_2} and Pa_{O_2} (by $\uparrow$ functional residual capacity, $\uparrow$end-inspiratory lung volume, $\uparrow V_A$, $\uparrow$ Fi_{CO_2})
- To $\downarrow$ work of breathing (e.g. to overcome respiratory muscle fatigue)
- To $\uparrow$ functional residual capacity (e.g. $\uparrow$ Pa_{O_2}, $\downarrow$ ventilator-induced injury)
- To stabilise the chest wall in severe chest injury

INITIATION OF INTUBATED MECHANICAL VENTILATION

A manual resuscitation circuit, mechanical ventilator and equipment for safe endotracheal intubation (Ch. 29) should be available. Initial ventilator settings are commonly set to achieve adequate oxygenation and V_A; however, this will depend upon the patient's condition. Common settings are: V_T 6–8 mL/kg, f 10–20 breaths/min, PEEP 5 cmH_2O, and Fi_{O_2} 1.0, and these will need to be adjusted according to the specific pathophysiology and response.

MANUAL RESUSCITATION CIRCUITS

Manual resuscitation circuits are primarily used to provide emergency ventilation when spontaneous effort is absent or inadequate. They may be used with a face or laryngeal mask, or an endotracheal tube. Occasionally they are used to provide a high inspired O_2 concentration during spontaneous breathing; however, this may impose significant additional respiratory work.[41] In the ICU they are commonly used for preoxygenation and manual lung inflation.

Their basic design includes a fresh gas flow of O_2, a reservoir bag and valves to allow spontaneous or positive-pressure breathing. Most manual resuscitation circuits use a self-inflating reservoir bag since this allows the circuit to be used by unskilled personnel and does not require a fresh gas flow. However, circuits using reservoir bags that are not self-inflating are still used in some institutions since they allow a better manual assessment of the respiratory mechanics, the 'educated hand', and it is clear when there is an inadequate seal with a mask. Oxygen-powered manually triggered devices have been used for many years; however, this has declined markedly since high $\dot{V}$ and P may lead to barotrauma or gastric inflation.

Self-inflating reservoir bags use a series of one-way valves to allow fresh gas flow oxygen and entrained air

to fill the bag. Inspired oxygen fractions as high as 0.8 may be achieved with neonatal or paediatric bags when an additional reservoir bag is used to allow fresh gas flow filling during expiration, after the bag has refilled.[42] However, lower Fi_{O_2}s (~0.6) will be obtained with both conventional O_2 flow rates of 8–15 L/min, and usual V_T and f, with an adult bag. Generally the valves are simple flap or duckbill in nature, and both positive pressure and spontaneous ventilation are possible. The reservoir bag volume in adults is typically 1600 mL, and V_T can be judged from chest wall movement. It is essential these devices use standard 15/22 mm connectors to allow rapid connection to standard endotracheal tubes and ventilator circuits.

COMPLICATIONS OF MECHANICAL VENTILATION (Box 31.2)[26]

Although mechanical ventilation may be vital, it also introduces numerous potential complications. Monitoring includes a high nurse : patient ratio (usually 1 : 1), ventilator alarms, and pulse oximetry. Capnography is required to confirm endotracheal tube placement, both at the time of intubation and during ventilatory support, and may be used to monitor the adequacy of V_A; however, expired CO_2 is strongly influenced by factors that alter alveolar dead space such as cardiac output. Intermittent blood gases, $PEEP_i$, airway pressures in volume-preset modes and V_T in pressure-preset modes should be recorded. Individual patients may benefit from more extensive monitoring of their respiratory mechanics or tissue oxygenation.

The patient's airway (i.e. patency, presence of leaks and nature and amount of secretions), breathing (i.e. rate, volume, oxygenation), and circulation (i.e. pulse, blood pressure and urine output) must be monitored. Ventilatory and circuit alarms should be adjusted to monitor an appropriate range of V, P and temperature. This should alert adjacent staff to changes in P and/or V that may be caused by an occluded endotracheal tube, tension pneumothorax or circuit disconnection. These alarms may be temporarily disabled while the cause is detected, but never permanently disabled. Sudden difficulties with high P during volume-preset ventilation or oxygenation must initiate an immediate search for the cause. This should start with the patency of the airway, followed by a structured approach both to the circuit and ventilator, and to factors altering the E and R of the lung and chest wall such as bronchospasm, secretions, pneumothorax and asynchronous breathing. In addition to careful clinical examination an urgent chest radiograph and bronchoscopy may be required.

Mechanical ventilation is also associated with a marked increase in the incidence of nosocomial pneumonia due to a reduction in the natural defenses of the respiratory tract, and this represents an important advantage offered by NIV. In patients successfully managed with NIV, Girou and colleagues reported a reduction in the incidence of nosocomial pneumonia, associated with improved survival, compared to IV.[43] Erect versus semirecumbent posture[44] also reduces the incidence of ventilator-associated pneumonia.

Whereas lung overdistension may result in alveolar rupture leading to pulmonary interstitial air, pneumomediastinum or pneumothorax, it may also lead to diffuse alveolar damage similar to that found in ARDS. Both are termed VILI, and V_T reduction leads to a marked decrease in ARDS mortality, due to a reduction in multiple organ dysfunction[5] (Ch. 33). Laboratory data suggest that inadequate PEEP with tidal recruitment and derecruitment of alveoli also leads to VILI; however, this has not been proven in a clinical trial. Finally, patient–ventilator asynchrony may result in wasted respiratory work, impaired gas exchange and respiratory distress (see below).

Positive-pressure ventilation elevates intrathoracic pressure, which reduces venous return, right ventricular preload and cardiac output. The impact is reduced by hypervolaemia, and partial ventilatory support

Box 31.2 Complications of intubation and mechanical ventilation

Equipment
- Malfunction or disconnection
- Incorrectly set or prescribed
- Contamination

Pulmonary
- Airway intubation (e.g. damage to teeth, vocal cords, trachea; see Ch. 29)
- Ventilator-associated pneumonia (reduced lung defence; see Ch. 36)
- Ventilator-associated lung injury (e.g. diffuse lung injury due to regional overdistension or tidal recruitment of alveoli)
- Overt barotrauma (e.g. pneumothorax)
- O_2 toxicity
- Patient–ventilator asynchrony

Circulation
- ↓ Right ventricular preload →↓ cardiac output
- ↑ Right ventricular afterload (if the lung is overdistended)
- ↓ Splanchnic blood flow with high levels of positive end-expiratory pressure (PEEP) or mean P_{aw}
- ↑ Intracranial pressure with high levels of PEEP or mean P_{aw}
- Fluid retention due to ↓ cardiac output →↓ renal blood flow

Other
- Gut distension (air swallowing, hypomotility)
- Mucosal ulceration and bleeding
- Peripheral and respiratory muscle weakness (see Ch. 57)
- Sleep disturbance, agitation and fear (which may be prolonged after recovery)
- Neuropsychiatric complications

where patient effort and a reduction in pleural pressure augments venous return. Secondary effects include a reduction in regional organ blood flow leading to fluid retention by the kidney, and possibly impaired hepatic function. This latter effect is seen only at high levels of PEEP where an increase in resistance to venous return and a reduction in cardiac output may combine to reduce hepatic blood flow.

Sleep disturbance, delirium and discomfort are common in mechanically ventilated patients. These effects may be reduced with analgesia and sedation until weaning is planned; however, it is also important not to prolong mechanical ventilation due to excessive use of sedatives, which may also depress blood pressure and spontaneous respiratory effort. A recent large clinical trial found no advantage of daily sedation over continuous infusion of sedation targeted to the lowest effective dose.[45] Both methods offer early mobilisation in ventilated subjects, shorter duration of ventilation, reduced delirium, ICU and hospital length of stay, and improved mortality and functional outcomes.[46,47] However, this direction must be balanced with strategies such as use of neuromuscular blockers in the first 48 hours of mechanical ventilation in ARDS, which reduced mortality,[48] which prevent or reduce asynchronous ventilatory effort.

Although pulmonary function has generally recovered by 12 months, complex neuropsychological and physical sequelae persist to at least 5 years in surviving ARDS patients.[49] Cognitive impairment has been associated with hypotension, hypoxaemia and hyperglcaemia. In addition anxiety, depression and post-traumatic stress disorder are common and appear to be associated with the severity of illness, duration of mechanical ventilation and premorbid factors including depression. All of these issues are increasingly important as improvements in care and greater numbers of patients treated result in more survivors from critical illness. Of particular note it appears that early interventions can be effective, but that late interventions fail to improve outcomes.

WITHDRAWAL (WEANING) FROM MECHANICAL VENTILATION

Once the underlying process necessitating mechanical ventilation has started to resolve, withdrawal of ventilatory support should be considered; increased duration of ventilation leads to a progressive rise in complications such as ventilator-associated pneumonia. However, other important parameters that must be considered include the neuromuscular state of the patient (ability to initiate a spontaneous breath), adequacy of oxygenation (typically low requirements for PEEP (5–8 cmH_2O) and Fi_{O_2} (<0.4–0.5]), and cardiovascular stability.[50] Once a patient is considered suitable to wean, a secondary question is whether an artificial airway is still required for airway protection or suction of secretions. Many patients can rapidly make the transition from mechanical ventilation to extubation, but ~20% of patients fail weaning despite meeting clinical criteria.[21] Advanced age, prolonged mechanical ventilation and chronic obstructive pulmonary disease all increase the likelihood that weaning will be difficult.[21]

Weaning failure is usually associated with an increase in respiratory drive, and respiratory rate and a fall in V_T, which contributes to hypercapnea;[51] about 10% of patients fail due to central respiratory depression. Various indices such as maximal inspiratory pressure (MIP), minute ventilation (V_E), f, V_T, f/V_T ratio and the CROP index have been investigated as predictors of weaning failure (**Table 31.1**). They are rarely used alone and careful clinical assessment is often adequate, yielding a re-intubation rate as low as 3%,[52] and none of these indices assess airway function following extubation. Although the typical threshold value for the rapid shallow breathing index (f/V_T ratio) is >105, a large recent multicentre study reported progressive increase in risk as this increased with a threshold of 57; in addition a positive fluid balance immediately prior to extubation was a significant risk factor for re-intubation.[53] Consequently, weaning indices should not necessarily delay extubation or a weaning trial. However, they

Table 31.1 Sample of measurements that have been used to predict successful outcome from weaning in critically ill patients*

PARAMETER	TYPICAL THRESHOLD VALUE†	COMMENT
V_E	≤15 L/min	Moderate to high sensitivity, low specificity
MIP	≤–15 cmH_2O	High sensitivity, low specificity
CROP index#	≥13	Moderate to high sensitivity, modest specificity
DURING A SPONTANEOUS BREATHING TRIAL		
f	≤38 breaths/min	High sensitivity, low specificity
V_T	≥325 mL (4 mL/kg)	High sensitivity, low specificity
f/V_T	≤105	High sensitivity, moderate specificity

#CROP index=(C_{dyn}×MIP×[Pa_{O_2}/PA_{O_2}]/f).[22]
Abbreviations: MIP=maximal inspiratory pressure; CROP=compliance, respiratory rate, oxygenation, maximal inspiratory pressure.
*See reference 50 for further detail.
†Although threshold values are often used, the data are not dichotomous. For example, as the f/V_T ratio increases, so does the rate of re-intubation.[53]

may quantitate important issues in the general clinical assessment, and may be directly relevant for a given patient. For example, frequent small V_T, an inadequate vital capacity (less than 8–12 mL/kg), large minute ventilation (≥15 L/min), depressed respiratory drive, and reduced respiratory muscle strength (MIP ≤ –15 cmH_2O), or drive should be strongly factored into deciding whether a patient is ready to safely undergo a trial of weaning.

Direct comparisons between T-piece trials, PSV and SIMV as weaning techniques have been performed in patients previously failing a 2-hour trial of spontaneous breathing. In the study by Brochard and colleagues,[54] PSV led to fewer failures and a shorter weaning period. In contrast Esteban and coworkers[55] found that a once-daily trial of spontaneous breathing resulted in the shortest duration of mechanical ventilation; however, a relatively high proportion of patients required re-intubation (22.6%). Viewed together these studies suggest that weaning was slower with SIMV,[19] although SIMV with PSV was not studied, and that either PSV or a T-piece trial are the preferred methods for weaning. Since low levels of PSV can help compensate for the additional work of breathing attributable to the endotracheal tube and circuit, some clinicians use low levels of PSV (5–7 cmH_2O) during weaning or during a spontaneous breathing trial. However, the work of breathing following extubation is usually higher than expected, probably due to upper airway oedema and dysfunction, so that work is similar to that during a T-piece trial.[22,23]

Re-intubation is relatively common, with reported rates of 15%, and is associated with a 7–11 fold increased risk of hospital death.[19] Although this may reflect extubation of sicker patients, there does appear to be a specific effect of extubation failure on outcome perhaps due to the risks of re-intubation itself along with its haemodynamic consequences, and an increased risk of infection. Thille and co-workers[56] reported that 27% of patients developed pneumonia, and that 50% of patients died following re-intubation. They identified age >65 years and underlying cardiorespiratory disease as risk factors for extubation failure. Unplanned extubations were associated with higher endotracheal tube position on chest radiograph. Hence, an important goal during mechanical ventilation will be to proceed to early and expeditious extubation with a low reintubation rate.

PATIENT–VENTILATOR INTERACTION

During partial ventilatory support or spontaneous breathing, the ventilator should match neural drive; however, suboptimal patient–ventilator interaction, also termed asynchrony, is common, frequently not diagnosed and is associated with prolonged mechanical ventilation, increased length of stay both in hospital and in the ICU, and with increased mortality when more than 30% of breaths are asynchronous.[57] Clinical signs of asynchrony include agitation, diaphoresis, tachycardia, hypertension and failure of weaning or NIV. Once this pattern is identified it is crucial that airway complications (partial obstruction, displacement) or a major change in the clinical state (e.g. pneumothorax, acute pulmonary oedema) are excluded before considering problems with patient–ventilator interaction.

Although both PAV and NAVA reduce asynchrony, they are complex and less commonly used. Recognition and management of asynchrony are assisted by a physiological approach to the respiratory cycle: (a) triggering of inspiration, (b) inspiration and (c) cessation of inspiration. Difficulties at each of these phases will lead to changes in respiratory drive and effort that may be expressed throughout the respiratory cycle. Careful bedside observation of the patient–ventilator interaction is essential as isolated observation of P, V and $\dot{V}$ waveforms displayed by the ventilator leads to under recognition of asynchrony. In one series[58] ineffective triggering accounted for most of the asynchronous episodes with autocycling the next most common cause. Prevalence of asynchrony increased with PSV ≥ 12 cmH_2O, large V_T and low respiratory rates in part reflecting dynamic hyperinflation and $PEEP_i$.

TRIGGERING OF INSPIRATION

1. $PEEP_i$ is an important hindrance to the triggering of inspiration in patients with severe air-flow limitation, since their inspiratory muscles must first reduce P_{ao} below ambient pressure.[59] Consequently P_{mus} must exceed $PEEP_i$ prior to triggering an assisted breath usually by either reducing airway pressure (pressure trigger) or reducing circuit flow (flow trigger). This inspiratory threshold load may be up to 40% of the total inspiratory work in acute respiratory failure when dynamic hyperinflation is present, and commonly results in ineffective triggering. Triggering can be markedly improved and respiratory work reduced by low levels of $PEEP_e$;[37,60] commonly 80–90% of dynamic $PEEP_i$[61] if this is measured.
2. Patient effort may be sensed, and the ventilator cycled (triggered) to inspiratory assistance, by changes in any of P_{ao}, flow, volume, shape-signal and detection of neural drive (NAVA). During pressure triggering a fall in P_{ao} is usually sensed at the expiratory block of the ventilator. Sensing at the Y-piece is not superior since there is a similar delay in sensing as the transducer is usually sited in the ventilator with a similar or greater length of gas tubing. Flow triggering senses a fall in continuous circuit flow, and was introduced as a method of reducing inspiratory work. However, there has been a marked improvement of both pressure and flow triggering in modern ventilators with the trigger time delay falling from ~400 ms to <60 ms in most modern ventilators,[62] and a similar improvement in the maximum fall in

airway pressure;[63] consequently ventilator triggering contributes about 5% of respiratory effort. Attempts to improve the trigger function by oversetting the pressure sensitivity (<–0.5 cmH_2O) may lead to autocycling, which may also occur with overset flow triggering. This is due to the P and $\dot{V}$ effects of cardiac oscillations, hiccups, circuit rainout or mask leak with NIV, and has been reported as a cause of apparent respiratory effort in brain-dead patients.[64] Flow triggering reduces the risk of autocycling at a given trigger sensitivity, and reduces respiratory effort a small amount compared with pressure triggering; however, it does not alter the frequency of ineffective efforts, or patient effort following triggering.[55] A combination of shape-signal and volume triggering is used on the Vision (Philips Respironics) ventilator; the increased sensitivity of shape-signal triggering reduces effort but increases autocycling.[55]

INSPIRATION

Once inspiration is triggered or sensed by the ventilator, $\dot{V}$ is determined by P, Ti or $\dot{V}$. For example during PSV ventilation a target P is held until expiration is sensed, and during ACV $\dot{V}$ is held for a set T_i. During ACV there may be continued inspiratory effort, and since inspiratory $\dot{V}$ is fixed, this will be reflected by a scalloping of the P_{ao}–T graph if $\dot{V}$ is inadequate. Again this may be illustrated using the equation of motion:

$$P_{mus} + P_{ao} = E_{rs} \cdot V + R_{rs} \cdot \dot{V} + P_o \qquad (31.9)$$

P_{mus} will reflect the difference between P_{ao} due to E, R and P_o and the observed P_{ao}. In contrast, during P-cycled ventilation (PACV) greater patient effort is rewarded and inspiratory work is lower than during equivalent ACV.[65]

Modern ventilators allow adjustment of inspiratory $\dot{V}$ and $\dot{V}$ pattern, and the rate of rise of P_{ao}. Low inspiratory $\dot{V}$ rates during ACV results in significant inspiratory work, but this may be markedly reduced by increasing inspiratory $\dot{V}$ to 65 L/min.[66] However, these issues are quite complex, and f increases (probably due to a lower respiratory tract reflex) as $\dot{V}_I$ increases,[67] reducing Te, which may contribute to dynamic hyperinflation in patients with severe air-flow obstruction. During PSV and PACV, many ventilators allow adjustment of the rate of rise of P to its target. Although an excessively steep P ramp leads to earlier attainment of the P target and greater early $\dot{V}$ rates, this is associated with increased dyspnoea and effort, as is too flat a P ramp.[55]

CESSATION OF INSPIRATION

During PSV, an increase in airway resistance will result in a longer expiratory time constant and a delayed fall in $\dot{V}_I$. Since this is the usual trigger for cycling to expiration, the ventilator may continue to provide $\dot{V}_I$ while the patient desires to exhale. This commonly leads to recruitment of expiratory muscles, detected both clinically and as a transient rise in the end-inspiratory P_{ao}.[68] Some modern ventilators allow control of the fall in $\dot{V}_I$ that is sensed as end inspiration; the default is usually a reduction of $\dot{V}_I$ to 25% of the peak $\dot{V}_I$ rate. When airway resistance is high a higher cycling threshold (e.g. 45%) can reduce T_i, V_T and $PEEP_i$ with reduced trigger effort. However, this may result in premature termination of inspiration in ARDS where the time constant is short. High levels of PSV (≥20 cmH_2O), weak respiratory muscles and mask leak with NIV are other common causes of asynchrony at the termination of inspiration. In this last group, PACV, which is time cycled, allows improved patient–ventilator synchrony at end-inspiration compared with PSV.[69]

High V_T, commonly associated with high levels of PSV often precedes wasted efforts due to shortened T_e and $PEEP_i$. As asynchrony is reduced with less PSV, the optimum level of PSV will occur when there is minimal increase in f and P_{mus}. This typically occurs at a PSV of 13 cmH_2O with V_T 6 ml/kg and T_i 0.8 seconds.[70]

Humidification and inhalation therapy

Steven T Galluccio and Andrew D Bersten

The upper airway normally warms, moistens and filters inspired gas. When these functions are impaired by disease, or when the nasopharynx is bypassed by endotracheal intubation, artificial humidification of inspired gases must be provided.

PHYSICAL PRINCIPLES

Humidity, the amount of water vapour in a gas, may be expressed as:

- *absolute humidity (AH):* the total mass of water vapour in a given volume of gas at a given temperature (g/m^3)
- *relative humidity (RH):* the actual mass of water vapour (per volume of gas) as a percentage of the mass of saturated water vapour, at a given temperature. Saturated water vapour exerts a saturated vapour pressure (SVP). As the SVP has an exponential relation with temperature (**Table 32.1**), addition of further water vapour to the gas can only occur with a rise in temperature
- *partial pressure.*

PHYSIOLOGY

Clearance of surface liquids and particles from the lung depends on beating cilia, airway mucus and transepithelial water flux. Airway mucus is derived from secretions from goblet cells, submucosal glands and Clara cells, and from capillary transudate. Conducting airways are lined with pseudostratified, ciliated columnar epithelium and numerous fluid-secreting glands. As the airway descends, the epithelium becomes stratified, and then cuboidal and partially ciliated, with very few secretory glands at the terminal airways. The cilia beat in a watery (sol) layer over which is a viscous mucous layer (gel), and move a superficial layer of mucus from deep within the lung toward the glottis (at a rate of 10 mm/min at 37°C and 100% RH). Both cilia function and mucus composition are influenced by temperature and adequate humidification.

The nasal mucosa has a large surface area with an extensive vascular network that humidifies and warms inhaled gas more effectively than during mouth breathing. Heating and humidification of dry gas are progressive down the airway, with an isothermic saturation boundary (i.e. 100% RH at 37°C or AH of 43 g/m^3) just below the carina.[1] Under resting conditions, approximately 250 mL of water and 1.5 kJ (350 kcal) of energy are lost from the respiratory tract in a day. A proportion (10–25%) is returned to the mucosa during expiration due to condensation.

The minimal moisture level to maintain ciliary function and mucus clearance is uncertain. Although reproducing an isothermic saturation boundary at the carina may be ideal, it does not seem essential in all situations. Mucus flow is markedly reduced when RH at 37°C falls below 75% (AH of 32 g/m^3), and ceases when RH is 50% (AH of 22 g/m^3).[2] This suggests that an AH exceeding 33 g/m^3 is needed to maintain normal function. Mucociliary function is also impaired by upper respiratory tract infection, chronic bronchitis, cystic fibrosis, bronchiectasis, immotile cilia syndrome, dehydration, hyperventilation, general anaesthetics, opioids, atropine and exposure to noxious gases. High fractional inspired oxygen concentrations (Fi_{O_2}) may lead to acute tracheobronchitis, with depressed tracheal mucus velocity within 3 hours.[3] Inhaled β_2-adrenergic agonists increase mucociliary clearance by augmenting ciliary beat frequency, and mucus and water secretion.[4]

CLINICAL APPLICATIONS OF HUMIDIFICATION

TRACHEAL INTUBATION

The need for humidification during endotracheal intubation and tracheostomy is unquestioned. As the upper airway is bypassed, RH of inspired gas falls below 50% with adverse effects, including:[5]

- increased mucus viscosity
- depressed ciliary function
- cytological damage to the tracheobronchial epithelium, including mucosal ulceration, tracheal inflammation and necrotising tracheobronchitis[6]
- microatelectasis from obstruction of small airways, and reduced surfactant leading to reduced lung compliance
- airway obstruction due to tenacious or inspissated sputum with increased airway resistance.

Metaplasia of the tracheal epithelium occurs over weeks to months in patients with a permanent tracheostomy.

Table 32.1 Relationship of temperature and saturated vapour pressure

TEMPERATURE (°C)	SATURATED VAPOUR PRESSURE (mmHg)	(kPa)	ABSOLUTE HUMIDITY (g/m³)
0	4.6	0.6	4.8
10	9.2	1.2	9.3
20	17.5	2.3	17.1
30	31.3	4.2	30.4
34	39.9	5.3	37.5
37	47.1	6.3	43.4
40	55.3	7.4	51.7
46	78.0	10.4	68.7

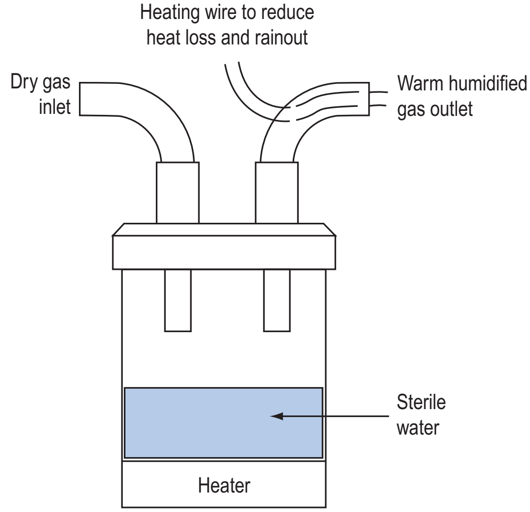

Figure 32.1 Hot-water 'blow-by' humidifier.

These patients do not usually require humidified gas, suggesting that humidification occurs lower down the respiratory tree. Nevertheless, humidification of inspired gas may be needed during an acute respiratory tract infection.

HEAT EXCHANGE

The respiratory tract is an important avenue to adjust body temperature by heat exchange. Humidification of gases reduces the fall in body temperature associated with anaesthesia and surgery.[5] Excessive heat from humidification may produce mucosal damage, hyperthermia and overhumidification.[7] However, if water content is not excessive, mucociliary clearance is unaffected up to temperatures of 42°C. Overhumidification may increase secretions and impair mucociliary clearance and surfactant activity, resulting in atelectasis.[6]

IDEAL HUMIDIFICATION

The basic requirements of a humidifier should include the following features:[8]

- the inspired gas is delivered into the trachea at 32–36°C with a water content of 30–43 g/m³
- the set temperature remains constant and does not fluctuate
- humidification and temperature remain unaffected by a large range of fresh gas flows, especially high flows
- the device is simple to use and to service
- humidification can be provided for air, oxygen or any mixture of inspired gas, including anaesthetic agents
- the humidifier can be used with spontaneous or controlled ventilation
- there are safety mechanisms, with alarms, against overheating, overhydration and electrocution
- the resistance, compliance and dead-space characteristics do not adversely affect spontaneous breathing modes
- the sterility of the inspired gas is not compromised.

METHODS AND DEVICES

WATER-BATH HUMIDIFIERS

Inspired gas is passed over or through a water reservoir to achieve humidification. Their efficiency is dependent on ambient temperature and the surface area available for gas vaporisation.

Cold-water humidifiers

These units are simple and inexpensive, but are inefficient, with a water content of around 9 g/m³ (i.e. about 50% RH at ambient temperatures). They are also a potential source of microbiological contamination. Routine use of cold-water humidifiers to deliver oxygen with simple facemasks is both unnecessary and at risk of suggesting the gas is adequately humidified.

Hot-water humidifiers **(Figs 32.1 and 32.2)**

Inspired gas is passed over (blow-by humidifier) or through (bubble or cascade humidifier) a heated-water reservoir. Gas leaving the reservoir theoretically contains high water content. The water bath temperature is thermostatically controlled (e.g. at 45–60°C) to compensate for cooling along the inspiratory tubing targeting an inspired RH of 100% at 37°C. A heated wire may be sited in the inspiratory tubing to maintain preset gas temperature and humidity. It is commonly believed that hot-water humidifiers do not produce aerosols, but microdroplets (mostly less than 5 μm diameter) have

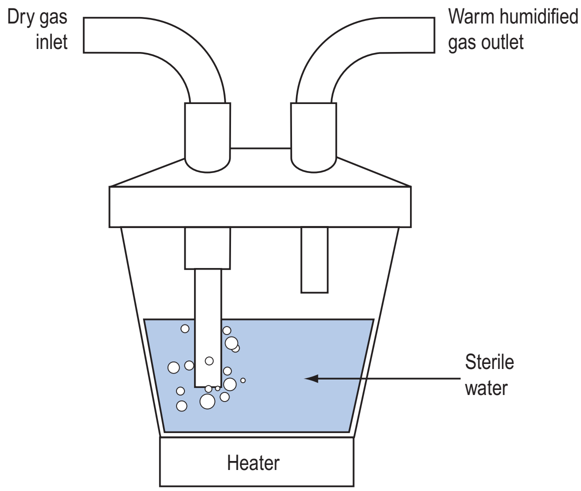

Figure 32.2 Hot-water 'cascade' or 'bubble' humidifier.

been reported with bubble humidifiers,[9] and this may be a potential source of infection.

Fisher–Paykel humidifier This is a commonly used blow-by humidifier. The delivery hose is heated by an insulated heating wire to achieve a manual preset inspired temperature. Audible alarms indicate disconnection and variations over 2°C from the set delivery temperature. The heater base is protected from overheating by a thermostat set at 47°C. If this fails, another safety thermostat operates at 70°C. A disposable humidification chamber is filled manually with water or by a gravity-feed set. To minimise rainout, the chamber outlet can be set at a temperature below the delivery hose outlet temperature; 2–3°C is usually adequate and does not compromise RH. Temperature alarms are fixed at 41°C and 29.5°C, with a back-up safety set at 66°C for the delivery chamber.

Although these humidifiers are often regarded as providing optimal humidification in ventilated patients, their performance is lower than expected both in practice and under optimal conditions in bench studies.[10] Under conditions of high ambient and/or high ventilator output temperature, the inlet temperature to the humidification chamber can be high enough that the heater base operates at a low enough temperature that humidification is impaired, with reduction in inspired water content.[10] The automatic compensation now available on this humidifier helps compensate for poor performance, which can also be prevented by setting the chamber outlet and hose to 40°C. High minute ventilation is well tolerated, but a small decrease in water content output has also been found with higher respiratory rates.[11]

HEAT AND MOISTURE EXCHANGERS

HMEs are popular intensive care unit (ICU) humidifiers due to their simplicity and increased efficiency. Modern HMEs are light with a small dead space (30–95 mL), but show great heterogeneity in humidity output, often not matching manufacturer-claimed performance.[12]

Hygroscopic HMEs adsorb moisture on to a foam or paper-like material that is chemically coated (often calcium chloride or lithium chloride), and this tends to increase their efficiency (i.e. AH around 30 g/m^3) compared with hydrophobic HMEs (i.e. AH 20–25 g/m^3).[13–18] Such hydrophobic HMEs possess antimicrobial properties and may act as a microbial filter (HMEF). These filters can have efficiencies greater than 99.9 977%,[19] i.e. less than 23 out of 1 million bacteria will pass through (filters that can exclude all virus particles are not currently available). Modern HMEs include both hydroscopic and hydrophobic properties. However, since nosocomial pneumonia is primarily due to aspiration of oropharyngeal secretions followed by secondary ventilator tubing colonisation, HMEs have not been shown to reduce the frequency of nosocomial pneumonia more than hot-water humidifiers when compared during prolonged ventilation.[19–21]

The efficiency of older HMEs decreases with time;[11] however, modern HMEs may retain their ability to humidify for prolonged periods with minimal change in resistance (a measure of tube patency and thus adequacy of humidification).[22,23] In patients undergoing invasive ventilation for a mean duration greater than 1 week there was no difference in endotracheal tube resistance between HME and active humidification.[23] However, allocation of humidification device was not randomised but based on perceived clinical need. Consequently, HMEs that achieve relatively high AH may be suitable for long-term mechanical ventilation in selected patients, particularly as the majority of reported HME complications (e.g. thick secretions and endotracheal tube occlusion) occur with units of lower humidification levels.[24–26] Nevertheless, HMEs increase dead space and imposed work of breathing, and cannot match the humidification offered by hot-water humidifiers, which remain the 'gold standard', particularly if secretions are thick or bloody, minute ventilation is high,[16,19,27] or in children and neonates.

COMPLICATIONS OF HUMIDIFICATION

INADEQUATE HUMIDIFICATION

An AH exceeding 30 g/m^3 is recommended in respiratory care.[27] Inadequate humidification is usually a problem only with HMEs. With hot-water humidifiers, however, efficiency is reduced by increasing gas flow rates and rainout. A decrease of about 1°C occurs for each 10 cm of tubing beyond the end of the delivery hose (i.e. the Y-connector and right-angled connector), and should be catered for. Inadequate humidification in high-frequency ventilation can be overcome by using superheated humidification of the entrained gas with a temperature thermistor built into the endotracheal tube.[24,28]

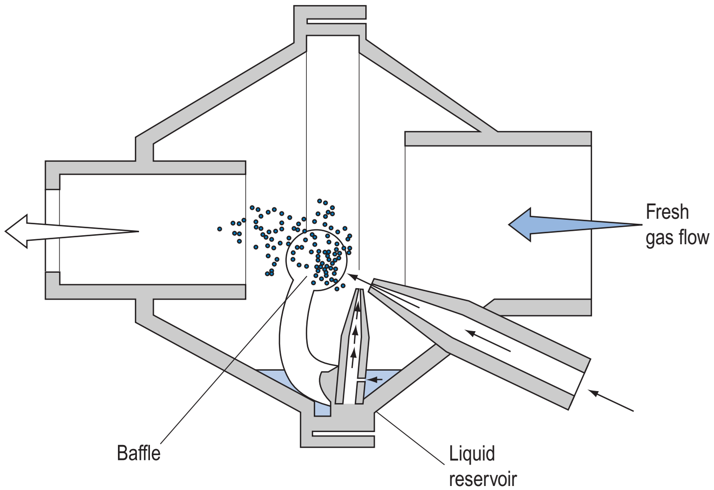

Figure 32.3 Sidestream nebuliser.

OVERHUMIDIFICATION

Overheating malfunction of hot-water humidifiers may cause a rise in core temperature, water intoxication, impaired mucociliary clearance and airway burns.[7]

IMPOSED WORK OF BREATHING

The work of breathing imposed by a humidifier is primarily resistive work and increases with inspiratory flow rate; the progressive increase in water content of HMEs is also associated with increased resistance.[29] The Fisher–Paykel humidifier imposes relatively low work compared with a bubble humidifier,[30] and HMEs typically have a resistance of 2.5 cmH_2O/L per second.[16]

INFECTION

Humidifiers do not appear to be an important factor in nosocomial respiratory tract infection. Although water reservoirs represent a good culture medium for bacteria such as *Pseudomonas* species, it is rare to culture bacteria from humidifiers, and is usually preceded by colonisation of the circuit by the patient's own flora within the first 24 hours of use.[31,32] Indeed, the incidence of nosocomial pneumonia is reported to be higher (due to outside contamination) if the circuit is changed too frequently (every 24 or 48 h).[32,33]

HUMIDIFICATION DURING NON-INVASIVE VENTILATION (NIV)

The hygrometric effects of NIV depend upon several factors, including type of ventilator (conventional versus turbine), V_T, peak inspiratory flow rates, Fi_{O_2} and degree of mask leak.[34,35] NIV applied without artificial humidification has been associated with accumulation of dried secretions in the oropharynx with subsequent aspiration, difficult intubation or frank airway obstruction.[36] In healthy volunteers, a delivered AH of at least 15 mgH_2O/L was necessary to ensure comfort during NIV.[37] This level is achievable with either passive or active humidification, but a higher humidity output may be required for patients with respiratory failure. Although there is a lack of robust data, current guidelines advocate the use of heated humidification over HMEs.[27]

HUMIDIFICATION FOR OXYGEN THERAPY DURING SPONTANEOUS BREATHING

Despite the ubiquity of oxygen therapy, there is no evidence to guide the addition of humidification for spontaneously breathing patients. There is no particular oxygen flow rate or duration of exposure that mandates artificial humidification. However, patient discomfort during high-flow oxygen therapy is improved with the use of heated humidification compared with bubble humidifiers or no artificial humidification at all.[38,39] It is unknown to what extent patient discomfort signals inadequate humidification and the potential for complications such as deranged mucociliary transport or increased airway resistance.

INHALATION THERAPY

Therapeutic aerosols are particles suspended in gas that are inhaled and deposited within the respiratory tract. Numerous factors, including particle size, inertia and physical nature, gravity, volume and pattern of ventilation, temperature and humidity, airway geometry, lung disease and the delivery system, alter aerosol deposition. In general, particles of diameter 40 μm deposit in the upper airway, those of 8–15 μm deposit in bronchi and bronchioles, those of 3–5 μm deposit in peripheral conducting airways and those of 0.8–3.0 μm settle in lung parenchyma. Optimal particle size will depend on the clinical indication and agent used. Obviously, if an HME with filtration characteristics is being used, the aerosol needs to be delivered proximal to the filter.

AEROSOL DELIVERY

Therapeutic aerosols may be delivered by nebuliser (jet, ultrasonic or vibrating mesh), metered-dose inhaler (MDI) or dry-particle inhaler (DPI). Although each of these methods tends to be less efficient in ventilated patients, provided that care is taken to optimise their performance, each can provide equivalent clinical effect.

NEBULISERS[40]

The most common jet nebulisers are sidestream nebulisers. These use an extrinsic gas flow through a narrow orifice, to create a pressure gradient that draws the drug mixture from a liquid reservoir (i.e. Bernoulli's principle; **Fig. 32.3**). The gas is then directed at a baffle to reduce the mean particle size. This extrinsic gas flow (usually 3–10 L/min) adds to the inspiratory flow, and may increase patient tidal volume unless the ventilator automatically compensates, or the preset tidal volume is adjusted. Further, this additional gas flow may impair ventilator triggering since it may prevent the development of a negative pressure or necessary reduction in continuous flow needed. Mainstream nebulisers employ inspiratory gas flow to actuate nebulisation. These are commonly large-volume water nebulisers that entrain air to achieve fresh gas flow rates of 20–30 L/min.

Ultrasonic nebulisers use high-frequency sound waves (typically 1 MHz) to create an aerosol above a liquid reservoir, to produce small uniform droplets (<5 μm) and a high mist density (i.e. 100–200 g/m^3). Tidal volume is not altered; however, ultrasonic nebulisers may cause overhydration and increased airway resistance. Further drawbacks in the critical care setting include: size, poor battery life, and the potential for drug inactivation by ultrasonic waves and heating.[40,41]

More recent nebuliser designs have utilised a vibrating mesh or plate. Medication in solution or suspension is forced through multiple apertures in the mesh or plate to produce an aerosol. A variety of vibrating mesh nebulisers are commercially available; common features include aerosol generation with high fine-particle fraction and overall higher drug output with minimal residual volume compared with jet nebulisers; additional benefits over ultrasonic types are the lack of heating effect or potential for drug degradation.[40]

Nebuliser aerosol deposition is highly variable, with significant rainout in the ventilatory circuit, endotracheal tube and large conducting airways. In a bench study delivery ranged from 6% of nebuliser charge to 37% depending upon humidification and breath activation; parallel in vivo data were similar but found a 20-fold difference in drug delivery.[42] Numerous factors have been shown to improve aerosol deposition, but only some of these are commonly practised. For example, although heating and humidification reduce aerosol deposition ≈50% due to increase in both droplet size and rainout, regular circuit disconnection and exclusion of humidification prior to nebulisation are not practical. However, placement of the nebuliser in the inspiratory limb of the circuit less than 30 cm from the endotracheal tube allows this tubing to act as a spacer or aerosol-holding chamber. This reduces aerosol velocity and losses due to impaction. Inspiratory activation of the nebuliser increases deposition by two- and threefold under dry and humidified conditions respectively;[41] use of a large chamber fill, tidal volume of 500 mL or more and minimisation of turbulent inspiratory flow (low flow rate, prolonged inspiratory time) also augment aerosol delivery.[39]

METERED-DOSE INHALERS

MDIs contain drug in ethanolic solution with a hydrofluoroalkane (HFA) propellant, allowing a relatively fixed volume (i.e. dose) to be delivered with each actuation (e.g. 100 μg for salbutamol and 20 μg for ipratropium).[40,43] Aerosol delivery is approximately 4–6% in ventilated adults, but increases to 11% when a spacer chamber is used, which is similar to optimal no-spacer values reported in the ambulant population.[44] Similar to nebulisers, absence of humidification, inspiratory limb position, inspiratory activation and minimisation of turbulence by lowering inspiratory flow rate and prolonging inspiratory time will increase aerosol delivery. It is important to avoid use of an elbow adapter, because this has been associated with dramatic reductions in aerosol delivery and efficacy.

DRY-POWDERED INHALERS

DPIs are commonly used in ambulant practice. Their use is not recommended in patients undergoing mechanical ventilation since they are breath actuated (requiring inspiratory flow rates close to 60 L/min) and, moreover, circuit humidification can cause powder clumping with impeded aerosol formation.[45]

CLINICAL APPLICATIONS OF INHALATION THERAPY

HUMIDIFICATION

Humidifiers produce gas with a water content dictated by temperature and water vapour pressure, whereas nebulisers produce gas with a water content determined by the aerosol content. The latter can provide water to the respiratory tract, particularly if the water reservoir is heated to increase mist density. However, the risk of infection is increased, as droplets can carry bacteria to the alveoli. Consequently, only sterile water should be used to fill the reservoir, and all units should be regularly changed and sterilised.

MUCOLYTICS

The role of mucolytics to reduce viscosity of secretions in critically ill patients is unknown. Oral mucolytics such as acetylcysteine reduce exacerbations of chronic bronchitis and chronic obstructive pulmonary disease (COPD), although this appears to be isolated to subjects

not receiving inhaled steroids.[46] It is uncertain if this interaction applies to newer thiol derivatives (such as erdosteine[47] and carbocisteine[48]), which are also associated with reduced COPD exacerbations. Case reports of recombinant human DNase appear promising when standard regimens fail to clear thick secretions[44] but the main evidence base for DNase utility is in bronchiectasis specifically due to cystic fibrosis.[49]

BRONCHODILATOR THERAPY

Optimal aerosol delivery and bronchodilator response are extremely important in critically ill patients with severe air-flow limitation, and this can be achieved using either a nebuliser or MDI technique provided that care is taken to optimise performance. Efficacy of MDI administration is optimised by use of a spacer with actuation synchronised with the onset of inspiration.[40] The response can be judged clinically, and in ventilated patients monitored by changes in peak-to-plateau airway pressure gradient, calculated airways resistance and intrinsic PEEP. Numerous studies show effective bronchodilatation with β_2-agonists and anticholinergic agents such as ipratropium in ventilated patients, and their combination is more effective than a single agent alone.[44]

Bronchodilator dosing

Standard doses of salbutamol for acute asthma are 2.5–5 mg administered by a nebuliser or 4–6 puffs of an MDI (400–600 μg), but the bronchodilator response can be shorter lasting than in ambulatory subjects. Consequently, dosing should be 3–4-hourly. Ipatropium is usually administered as 0.5 mg by a nebuliser or four puffs (80 μg) of an MDI. Higher or more frequent drug dosing is often effective when there is severe, reversible air-flow obstruction, and continuous nebulisation of a β_2-agonist may be used in acute severe asthma until there has been a clinical response. If the patient is moribund with minimal ventilation or is unable to tolerate nebulisation, parenteral administration should be considered; however, under most circumstances there is no particular benefit with this route.[50]

NON-INVASIVE VENTILATION (NIV)

Optimal bronchodilator therapy for patients requiring NIV, particularly for acute exacerbations of COPD, is unknown. It is preferable not to interrupt NIV for this purpose and both nebulisers and MDIs appear effective during NIV.[44] Despite the potential for increased loss of nebulised drug in a high-gas-flow continuous positive-airways pressure circuit, good bronchodilator response with salbutamol has been reported in this setting.[51]

INHALED CORTICOSTEROIDS

Inhaled corticosteroids are recommended in persistent asthma[52] and severe chronic obstructive pulmonary disease with frequent exacerbations.[53] However, in acute episodes of these conditions, inhalational delivery does not preclude the need for systemic corticosteroid therapy.[54] Small-particle inhaled corticosteroids offer the theoretical benefit of improved total and peripheral lung distribution.[55] For example, ciclesonide has a mass median aerodynamic diameter (MMAD or particle size) of 1.1 μm versus a MMAD of 3.5 μm with CFC-propelled beclometasone.[55] Improvement in clinical end-points with these new formulations, particularly in mechanically ventilated patients, remains to be demonstrated.

DELIVERY OF ANTIBIOTICS AND ANTIVIRAL AGENTS

Aerosolised antibiotics have been contentious for many years; however, the potential to achieve high concentrations of antibiotics at the site of infection while minimising adverse effects remains appealing. In animal models of bronchopneumonia inhaled amikacin[56] and ceftazidime[57] achieved 3–30 times increases in lung tissue concentrations and better sterilisation of lung compared with intravenous administration. In humans, gentamicin by conventional intravenous dosing has been shown to reach only subinhibitory concentrations in the alveolar lining fluid.[58]

Numerous studies in patients with cystic fibrosis have shown a reduction in sputum volume and density of bacteria, and improved lung function with reduced risk of hospitalisation when inhaled aminoglycosides are used.[59,60] Similar results, including a reduction of markers of airway inflammation, have been reported with bronchiectasis,[61,62] and in mechanically ventilated patients with chronic respiratory failure.[63]

Three recent randomised controlled trials of adjunctive aerosolised antibiotics in ventilator-associated tracheobronchitis (VAT) and/or VAP have shown positive outcomes with reduction in the Clinical Pulmonary Infection Score, facilitation of weaning, or reduction in systemic antibiotic use.[64–66] Treatment protocols included amikacin 400 mg daily,[64] gentamicin 80 mg 8-hourly,[65] and vancomycin 120 mg 8-hourly.[66] The presumption of emerging bacterial resistance with increased aerosolised antibiotic use, akin to the known risk with systemic delivery, is not confirmed by the available data.[67] Paradoxically, emergence of resistance may be reduced via higher pathogen eradication rates, earlier intervention in treating VAT and reduced exposure to systemic therapy.[68]

Other antimicrobials that have been safely nebulised include colistin (polymyxin), aztreonam, amphotericin B and pentamidine. However, inhaled amphotericin may result in bronchospasm. Aerosolised ribavirin has limited evidence of benefit for respiratory syncytial virus infection.[69,70] Ribavirin deposition in the circuit may cause valve malfunction, and concerns of teratogenicity in health care personnel have dictated its use with care.[70]

SPUTUM INDUCTION

Nebulised 3% saline is effective in sputum induction for diagnosing *P. jirovecii* pneumonia in patients with the

acquired immunodeficiency syndrome (AIDS). The need for bronchoscopy can be obviated[71] with specificity of sputum induction approaching 100% and sensitivity of at least 55%.[72]

Sputum induction has been used to diagnose a number of other infections, and appears to be safe in patients with severe air-flow limitation.[73]

SURFACTANT THERAPY

Surfactant preparations have been delivered by instillation and as an aerosol in neonates with respiratory distress syndrome, and in adults with ARDS. Aerosolised surfactant could theoretically achieve more uniform distribution and avoid problems of instilling liquid into injured lungs. However, large amounts are needed for lung deposition, and preferential distribution occurs to less-damaged lung areas that receive better ventilation.[74] Clinical studies of exogenous surfactant in adult ARDS have not shown any mortality benefit, although novel preparations are currently being tested.[75]

INHALED NITRIC OXIDE

The therapeutic potential of inhaled nitric oxide (iNO) lies as a selective pulmonary vasodilator with minimal systemic side effects. iNO improves outcomes in newborns with persistent pulmonary hypertension.[76] In adult patients with ARDS, iNO results in an improvement in oxygenation in about 60–80% of patients with a 10% reduction in pulmonary arterial pressure.[77] However, these physiological benefits have not translated into effects on mortality or duration of mechanical ventilation.[78]

PROSTANOIDS[44]

Inhaled prostanoids target selective pulmonary vasodilatation to well-aerated areas, leading to similar improvements in oxygenation as iNO in patients with the acute respiratory distress syndrome. When delivered systemically these agents lead to impaired oxygenation and to hypotension due to non-selective pulmonary and systemic vasodilatation respectively. Iloprost (a synthetic epoprostenol/prostacyclin analogue) has a longer half-life (about 20–30 minutes compared with 3 minutes for prostacyclin), and is sometimes used for chronic pulmonary hypertension (2.5–5 mg 6–9 times per day), and similar doses can be used in mechanically ventilated patients. Treprostinil has a longer half-life still, allowing four times daily dosing.[79]

INHALED HELIUM MIXTURES

Helium is 7.2 and 8 times less dense than air and oxygen respectively. This property is useful in the setting of increased airways resistance as less turbulent and more efficient laminar flow is encouraged. Therefore, albeit an inert gas without any direct anatomical effect, helium can improve dynamic respiratory mechanics and reduce work of breathing. Effect size relates to the relative helium concentration, in practice at least 60–70% helium is required, limiting applicability to patients able to tolerate $F\text{i}_{O_2}$ of 30–40%. Helium–oxygen mixtures (heliox) potentially have a role in managing obstructive disease of both the upper and lower airways.[77] However, clinical use of heliox remains controversial and without evidence-based guidelines. In patients with COPD exacerbations, an open-label, randomised trial of 65% helium in oxygen versus $F\text{i}_{O_2}$ of 0.35 during NIV failed to demonstrate any significant improvement in duration of NIV or need to progress to intubation.[80] A larger multicentre study is currently under way.[81]

It should be noted that heliox as the driving gas in a ventilator circuit will influence the delivery of other inhaled agents. For example, aerosolised drug output from a MDI is increased, whereas output from a nebuliser is decreased.[77] As a further consideration, heliox may improve particle distribution to the peripheral small airways, perhaps as a function of reduced turbulence.[82]

Acute respiratory distress syndrome

Andrew D Bersten

The acute respiratory distress syndrome (ARDS) was first described in 1967 by Ashbaugh and colleagues as the 'acute onset of tachypnea, hypoxemia and loss of compliance after a variety of stimuli'.[1] Continued research examining the underlying mechanisms and management strategies is now translating into improved outcome.

DEFINITIONS

The ARDS Definition Task Force (the Berlin definition[2]) has recently revised the long-standing 1994 American–European Consensus Conference (AECC) definition[3] (**Table 33.1**). ARDS still refers to acute hypoxaemic respiratory failure due to bilateral and diffuse alveolar damage, and is now classified as mild, moderate and severe based on the Pa_{O_2}/Fi_{O_2} ratio (Table 33.1). The broad term 'acute lung injury' (ALI), which referred to cases with a Pa_{O_2}/Fi_{O_2} ratio <300, has been replaced and many concerns addressed. A minimum positive end-expiratory pressure (PEEP) of 5 cmH_2O is specified, and chest radiograph criteria and exclusion of hydrostatic oedema clarified, including examples. The lung injury score (LIS),[4] which uses a four-point score attributed to ranges of Pa_{O_2}/Fi_{O_2} ratio, PEEP, respiratory system compliance and the number of quadrants involved on chest radiograph has also been used to quantify severity of ARDS; however, as neither lung compliance nor dead space improved the predictive ability of the Berlin definition, the LIS may become less pertinent.

CHEST RADIOGRAPH AND CHEST CT IN ARDS

The intent of chest imaging is to exclude opacities due to pleural effusion, nodules, masses, collapse and pleural thickening, and that the infiltrate must be bilateral and consistent with pulmonary oedema.[2] Autopsy and chest radiographs of ARDS show a uniform process affecting both lungs. However, chest CT[5] has demonstrated marked heterogeneity of lung inflation in ARDS with a dorsal, dependent increase in lung density, and relatively normal inflation of ventral lung. In addition, CT frequently reveals previously undiagnosed pneumothorax, pneumomediastinum and pleural effusion. After the second week of mechanical ventilation CT scans may demonstrate altered lung architecture and emphysematous cysts or pneumatoceles.

CT numbers or Hounsfield units can be assigned to each voxel (~2000 alveoli in a standard 10-mm slice).[5] These data can then be used to assess what proportion of a region of interest is non-aerated, poorly aerated, normally aerated, or hyperinflated. Whole-lung CT allows (a) reconstruction of the upper and lower lobes (the middle lobe is difficult to separate), (b) the same section of lung to be studied at different levels of inflation or PEEP (the lung also moves in a cepahalo-caudad direction with respiration), and (c) a broader picture of the lung to be obtained (lung damage is heterogeneous in ARDS). However, whole-lung CT demands considerable exposure to ionising radiation, and different information, perhaps more pertinent to mechanical ventilation is obtained from dynamic CT.

Clinical assessment of chest CT is discussed in Chapter 39, and CT findings in ARDS are discussed below under Clinical management.

EPIDEMIOLOGY

Estimates of the incidence and outcome from ARDS vary widely due to differences in the definitions used, case-mix and local factors. Using the AECC definition the Australian incidence was 34 per 100 000 for ALI and 28 per 100 000 for ARDS;[6] recent US estimates were 79 and 59 per 100 000 respectively[7] – both much greater than many previous estimates. The Australian data equate to 1 in 10 non-cardiothoracic ICU patients developing ARDS, which reflects the tendency for clinicians to underestimate its incidence. However, the incidence of ARDS appears to be decreasing likely due to improvements in health care such as use of protective ventilation strategies, reduced transfusion-associated ALI (TRALI) and better management of sepsis.[8]

For many years the mortality for ARDS was reported to be ~60%; the Australian multicentre data reported mortality rates of 32% for ALI, and 34% for ARDS,[6] with US mortality rates a little higher at 38.5% and 41%.[7] Particular diagnostic groups such as multiple trauma have a lower mortality rate than other causes of ARDS, and patients with ARDS who have chronic liver disease, non-pulmonary organ dysfunction, sepsis or age greater than 70 years (hazard ratio 2.5)[9] have a higher risk of

Table 33.1 Criteria and classification of ARDS

	AECC DEFINITION#	BERLIN DEFINITION*
Onset	Acute (not defined) onset No risk factor formally defined	Within 7 days of a known risk factor (See Box 33.1)
Chest imaging	Bilateral opacities on chest radiograph	Bilateral opacities consistent with pulmonary oedema on either chest radiograph or CT
Pulmonary oedema	PAOP ≤ 18 mmHg when measured or no clinical evidence of raised left atrial pressure	Non-hydrostatic oedema; not fully explained by heart failure or fluid overload Echocardiography or another objective measure may be required
Classification	ALI $Pa_{O_2}/Fi_{O_2} \leq 300$ ARDS $Pa_{O_2}/Fi_{O_2} \leq 200$	Mild $200 < Pa_{O_2}/Fi_{O_2} \leq 300$ Moderate $100 < Pa_{O_2}/Fi_{O_2} \leq 200$ Severe $Pa_{O_2}/Fi_{O_2} \leq 100$

#No minimum ventilatory setting defined for Pa_{O_2}/Fi_{O_2} data
*Based on oxygenation measured on a minimum of 5 cmH_2O PEEP. For the mild classification only, oxygenation can also be assessed during non-invasive ventilation. For the moderate and severe classification the patient must be receiving intubated ventilatory assistance.

death. Clinical trial outcomes report low mortality rates in the control arm in part due to the exclusion of patients with limited life expectancy; consequently many factors need to be considered when assessing outcome prediction.

PULMONARY FUNCTION IN SURVIVORS

Respiratory function continues to improve after discontinuation of mechanical ventilation, and usually returns towards normal by 6–12 months.[10,11] Although a variety of abnormal pulmonary function tests may be found, impaired diffusing capacity is the most common. This is rarely symptomatic, but occasional patients have severe restrictive disease, and this is correlated with their cumulative LIS.[11]

QUALITY OF LIFE IN SURVIVORS

Compared with disease-matched ICU patients who do not develop ARDS, patients with ARDS have a more severe reduction in both pulmonary and general health-related quality of life.[12] Many patients have reduction in exercise tolerance that may be attributable to associated critical illness neuropathy and myopathy; nerve entrapment syndromes, contractures, postural hypotension, and heterotopic calcification may play a role in a minority.[10] When followed for 5 years in a young and severe cohort (median age 45 years) with relatively few prior comorbidities, there was persistent functional impairment with little improvement after 12 months.[13] Depression, anxiety and post-traumatic stress disorder are also common (20–50% of survivors). Finally, most survivors have cognitive impairments such as slowed mental processing, or impaired memory or concentration, and these correlate with the duration of ventilation, hyperglycaemia and variability in blood glucose, and the period and severity of desaturation <90%.[14,15]

Box 33.1 Clinical risk factors for ARDS

Direct	Indirect
Pneumonia	Non-pulmonary sepsis
Aspiration of gastric contents	Multiple trauma
Lung contusion	Massive transfusion
Fat embolism	Pancreatitis
Near drowning	Cardiopulmonary bypass
Inhalational injury	
Reperfusion injury	

In an analysis of survivors of the ARDS Network Fluid and Catheter Trial (FACTT),[16] Mikkelsen and co-workers[17] found that over half the subjects suffered from cognitive dysfunction and from psychological disability, and that these parameters were associated with lower Pa_{O_2}, enrolment in the restrictive fluid arm, and hypoglycaemia. Taken together these data caution against permissive hypoxaemia as a strategy to reduce ventilator-induced lung injury (VILI), and suggest that quality of survival is an important additional outcome for clinical trials.

PATIENTS AT RISK FOR ARDS

About one-third of critically ill patients exposed to either a direct or indirect risk factor (**Box 33.1**) develop ARDS, most within 6–48 hours. Multiple risk factors such as low pH, chronic alcohol abuse or chronic lung disease substantially increase the incidence of ARDS in at-risk patients. Diabetes reduces the risk of developing ARDS.[18]

PATHOGENESIS

Although it is well accepted that diffuse alveolar damage with: (a) pulmonary oedema due to damage of

the alveolocapillary barrier, (b) a complex inflammatory infiltrate and (c) surfactant dysfunction,[19] are essential components of ARDS, the sequence of events is uncertain and probably depends upon the precipitating insult and host response. For example in endotoxin-induced lung injury, hypoxaemia and reduced lung compliance occur well before recruitment of neutrophils or an increase in lung weight due to an increase in permeability.[20] In addition, typical of early ARDS, surfactant turnover is dramatically increased prior to these changes. Furthermore, epithelial lining fluid sampled immediately following intubation in patients with ARDS has markedly increased concentrations of type III procollagen peptide,[21] suggestive of fibrosing alveolitis extremely early in the course of lung damage.

THE ALVEOLOCAPILLARY BARRIER

The normal lung consists of 300 million alveoli with alveolar gas separated from the pulmonary microcirculation by the extremely thin alveolocapillary barrier (0.1–0.2 μm thick). Since the endothelial pore size is 6.5–7.5 nm, and the epithelial pore size is almost one-tenth that at 0.5–0.9 nm, the epithelium is the major barrier to protein flux.[22] The surface area of the alveoli is estimated to be 50–100 m^2, which is made up predominantly of alveolar type I cells, with the metabolically active type II cells accounting for ~10% of the surface area. In turn, these cells are covered by the epithelial lining fluid with an estimated volume of 20 mL, ~10% of which is surfactant, the rest being filtered plasma water and low-molecular-weight proteins and a small number of cells, mainly alveolar macrophages and lymphocytes.

In ARDS the alveolocapillary barrier is damaged with bidirectional leakage of fluid and protein into the alveolus and leakage of surfactant proteins and alveolar cytokines into the plasma. Total protein content in bronchoalveolar lavage (BAL) fluid is 20–100 times that found in both healthy subjects and ventilated subjects without cardiorespiratory disease.[23,24] There is also disruption of the epithelial barrier, surfactant dysfunction and proliferation of alveolar type II cells as the progenitor of type I cells. Indirect causes of ARDS cause pulmonary endothelial injury, followed by recruitment of inflammatory cells and then epithelial damage, whereas direct causes of ARDS cause epithelial injury and secondary recruitment of inflammatory cells. The outcome of these processes must reflect a balance between repair and fibrosing alveolitis.

CELL TYPES INVOLVED

The large surface area of pulmonary epithelium and endothelium including the associated microcirculation, myofibroblasts, and both alveolar macrophages and recruited neutrophils are all important components of acute lung injury. BAL fluid has a marked increase in cell count; alveolar macrophage numbers are increased about twofold, but as a fraction of the cell count falls from around 90% to 20–40% of the cell count due to a greater increase in neutrophils from around 1% to 50–80% of the cell count. In addition microparticles, tiny vesicles potentially derived from most of these cell types, are found in both BAL fluid and blood and may play an important role in both lung damage and repair.[25] A temporal trend towards more normal neutrophil and alveolar macrophage ratios in BAL fluid is associated with survival.

NEUTROPHILS

Neutrophils are the most abundant cell type found in both the epithelial lining fluid (e.g. BAL fluid), and alveoli in histological specimens from early in the course of ARDS. Although neutrophil migration across the endothelium and then the epithelium does not cause injury, when activated neutrophils are pro-inflammatory and pro-apoptotic, and release reactive oxygen species, cytokines, eicosanoids and a variety of proteases that may make an important contribution to basement membrane damage, increased permeability and direct cell damage. Following bone marrow demargination, activated neutrophils adhere to the endothelium on their passage to the alveolus, and this may be accompanied by an early, transient leucopenia. Although neutrophils have an important role in host defence due to their bactericidal activity, there is a marked (50–1000-fold) increase in the release of cytotoxic compounds when they are activated by adherence to the endothelium, epithelium or contact with interstitial extracellular matrix proteins.[26] The factors involved in adhesion of neutrophils are complex and involve the integrin family of proteins, selectins and a number of adhesion molecules.

In models of ARDS, antibodies to adhesion molecules (e.g. CD11b/CD18 antibodies) ameliorate lung injury, suggesting a crucial and central role of this cell type. However, ARDS occurs in neutropenic patients, and was not more common when granulocyte colony-stimulating factor was administered to patients with pneumonia.[27] Clearly, other cell types play an important role, and neutrophil chemoattractants such as IL-8 must be present in the lung prior to neutrophil accumulation.

ALVEOLAR MACROPHAGES

Alveolar macrophages are the most common cell type normally found in BAL fluid, and together with interstitial macrophages play an important role in host defence and modulation of fibrosis. They are capable of releasing IL-6 and a host of mediators similar to the activated neutrophil, including TNF-α and IL-8 in response to stretch,[28] and may amplify lung injury. Macrophages also release factors such as TGF-α and PDGF that stimulate fibroblast proliferation, deposition

of collagen and glycosaminoglycans, angiogenesis and lung fibrosis.

A study using different cell markers found that there appear to be different pools of alveolar macrophages termed the M1 and M2 phenotype.[29] The M1 phenotype is characterised as a resident alveolar macrophage that is pro-inflammatory, and the M2 phenotype appears to represent recruited monocytes and be central to lung repair and fibrosis depending upon timing, local milieu and cross talk with other cell types. This may account for the observation that ARDS survivors progressively increase alveolar macrophage number; however, any conclusion awaits further work examining alveolar macrophage phenotypes and clinical outcomes.

EPITHELIUM

Alveolar epithelial type II cells are extremely metabolically active; they manufacture and release surfactant, along with type I cells control alveolar water clearance through epithelial Na channels and Na^{+}/K^{+} ATP-ase, express cytokines, which in turn interact with surfactant production, and are the progenitor of type I cells following injury. In response to both stretch and endotoxin, type II cells express IL-8 and TNF-α, with the latter cytokine augmenting Na^{+}, and hence water, egress from the alveolus.[30] Damage to the epithelium leads to dysfunctional surfactant release and impaired resolution of alveolar oedema which both reduces vectorial transport of Na^{+} in part through down-regulation of ion transport genes, and up-regulates gene expression of Il-8, TNF-α and IL-β.[31]

Epithelial biomarkers include surfactant protein B (SP-B), which is predictive of ARDS,[32] and SP-D, and the receptor for advanced glycation end-products (RAGE) both of which have been associated with severity and outcome of ARDS.

ENDOTHELIUM

Pulmonary endothelial cells express a variety of adhesion molecules and COX-2, secrete endothelin and cytokines including IL-8,[33] stimulate procoagulant activity and 'cross talk' with the alveolar macrophages and type II cells. In addition to generalised endothelial activation, the endothelium is subject to mechanical stress both secondary to vascular pressure, and its association with the alveolus. Plasma levels of von Willebrand factor antigen are both predictive of and associated with outcomes from ARDS[34]; however, as it is synthesised by all vascular endothelial cells it is a non-specific biomarker.

Microvascular thrombosis is common in ARDS, associated with inflammation, and contributes to pulmonary hypertension and wasted ventilation. Platelet aggregation contributes through release of thromboxane A_2, serotonin, lysosomal enzymes, and platelet-activating factor. Impaired fibrinolysis also contributes to these changes, and abnormal plasma levels of protein C and plasminogen activator inhibitor-1 are associated with outcome and organ failure in ARDS. Lung injury also leads to expression of the coagulation factor X on pulmonary epithelium, which appears to be a direct link between coagulation and pulmonary fibrosis.[35]

CHEMOKINES IN ARDS

The expression and secretion of chemokines (chemoattractant cytokines) at sites of inflammation is a key proximal step in initiating the inflammatory cascade. IL-8-induced chemotaxis and activation of neutrophils are elevated in ARDS BAL fluid both within hours of the initiating insult and before recruitment of neutrophils, and in a manner that reflects subsequent morbidity and mortality. IL-8 antibodies prevent recruitment of neutrophils and protect the lung. Indeed, the recruitment and retention of neutrophils requires the generation and maintenance of a localised chemotactic/haptotactic gradient.[36]

MEDIATORS IN ARDS[37]

Inflammation is usually a redundant process so that numerous mediators, including cytokines, chemokines, complement, reactive oxygen species, eicosanoids, platelet-activating factor, nitric oxide, proteases, growth factors and lysosomal enzymes, derived from a number of different cell types, play important roles in the pathophysiology of ARDS. As the alveolocapillary barrier becomes injured these are no longer compartmentalised in the alveolus, and many of these proteins have been measured in blood as well as in the epithelial lining fluid. Care must be taken when interpreting these data as immunological levels may not reflect biological activity, inhibitors or binding proteins may complex with the active protein or epitope and interfere with immunological detection, and the ultimate biological effect will depend upon a balance of pro-inflammatory and anti-inflammatory effects.

Of the pro-inflammatory mediators, TNF-α, IL-1β, IL–6 and IL-8 are the most important. However, even greater increases are found in their cognate receptors or antagonists such as the counter-regulatory cytokine IL-10, so that their biological impact is markedly reduced.[38] Blood or epithelial lining fluid levels are associated with mortality, but are rarely used clinically.

RESOLUTION OF ARDS AND THE DEVELOPMENT OF FIBROSING ALVEOLITIS

Although histological evidence of fibrosing alveolitis (mesenchymal cells and new vessels in alveoli) is not usually found until at least 5 days following the onset of ARDS, elevated levels of type III procollagen peptide are found in the epithelial lining fluid soon after diagnosis;[21] both oedema fluid and plasma levels are associated with mortality.

Clinical resolution of ARDS usually occurs provided that both the underlying cause is promptly and effectively treated, and that appropriate supportive care is provided. Alveolar oedema resolves with active transport of Na^+ by the type II cells followed by passive clearance of water through transcellular aquaporin channels; repair of the alveolocapillary barrier is associated with improved outcome. Type II cells proliferate and cover the denuded epithelium before differentiating into type I cells.

Both host response and the clinical course of ARDS influence lung remodelling in ARDS. Cross-talk between type II cells and alveolar macrophages, probably the M2 phenotype, along with epithelial mesenchymal transition – a process where reactive oxygen species, hypoxia, TGF-β and mechanical stress lead to altered epithelial transcription – are central to interstitial responses. Epithelial cells assume characteristics of mesenchymal cells with loss of polarity, increased resistance to apoptosis, and increased migration (into the interstitium) where they lay down a fibrotic matrix.[39]

CLINICAL MANAGEMENT OF ARDS

The factors leading to ARDS must be promptly and appropriately treated. This includes diagnosis and treatment of infection with drainage of collections and appropriate antimicrobial agents, recognition and rapid resuscitation from shock, splinting of fractures, and careful supportive care. Prevention of deep venous thrombosis, stress ulceration, nosocomial infection, and malnutrition, often with enteral nutrition, must all be considered.

Early mobilisation of mechanically ventilated patients accompanied by appropriate levels of analgesia and sedation is feasible and safe, and offers shorter duration of ventilation, reduced delirium, ICU and hospital length of stay, and improved mortality and functional outcomes.[40,41] However, this must be balanced with strategies such as use of neuromuscular blockers in the first 48 hours of mechanical ventilation in ARDS, which reduced mortality,[42] possibly through prevention or reduction of asynchronous ventilatory effort.

MECHANICAL VENTILATION

Acute hypoxaemic respiratory failure,[43] and an increase in the work of breathing, usually mandates mechanical ventilation (**Table 33.2**). The role of non-invasive ventilation in ARDS is contentious; there are no large definitive studies, and although some groups report encouraging results these are usually in patients with mild ARDS.[44] Failure of NIV is common, associated with greater complication rates and mortality, perhaps due to delayed intubation.[45-47] If non-invasive ventilation is considered in ARDS it requires particular care (see Ch. 37).

The method and delivery of ventilatory support must take into account both the pathophysiology of ARDS and ventilator-induced lung injury (VILI). The ARDS Network randomised 861 ALI patients from 75 ICUs to receive either a tidal volume (V_T) of 12 or 6 mL/kg predicted body weight.[48] Mortality was reduced by 22%, from 40% to 31%, in the lower V_T group. There was a strict PEEP and Fi_{O_2} protocol, and patients were ventilated with assist-control ventilation

Table 33.2 Pathophysiology of acute lung injury (ALI) and adult respiratory distress syndrome (ARDS)

FEATURE	CAUSE(S)
Hypoxaemia	True shunt (perfusion of non-ventilated airspaces) Impaired hypoxic pulmonary vasoconstriction V/Q mismatch is a minor component
↑Dependent densities (CT)	Surfactant dysfunction alveolar instability
(Collapse/consolidation)	Exaggeration of normal compression of dependent lung due to ↑weight (↑lung water, inflammation)
↑Elastance (↓compliance)	Surfactant dysfunction (↑specific elastance) ↓Lung volume ('baby lung') ↑Chest wall elastance Fibrosing alveolitis (late)
↑Minute volume requirement	↑Alveolar dead space (VD_{phys} V_t often 0.4–0.7) ↑V_{CO_2}
↑Work of breathing	↑Elastance ↑Minute volume requirement
Pulmonary hypertension	Pulmonary vasoconstriction (thromboxane A_2, endothelin) Pulmonary microvascular thrombosis Fibrosing alveolitis Positive end-expiratory pressure

to avoid excessive spontaneous V_T. Similar data with improved long-term survival are found in routine clinical practice[49]; however, it is the concept of lung protection rather than an exact V_T formula that is important.[50] As Hager and colleagues[51] found that lower V_T ventilation was protective across all quartiles of plateau pressure (P_{plat}) in the ARDS Network trial, with no safe upper limit of P_{plat}, it appears that the key variable is lower V_T rather than control of static airway pressure.

AVOIDANCE OF OVERSTRETCH AND INADEQUATE RECRUITMENT

The increase in dependent lung density found on chest CT, due to non-aerated and poorly aerated lung, reduces the volume of aerated lung available for tidal inflation (baby lung). Both PEEP and tidal recruitment will increase aeration of some of these air spaces, but a V_T that is not reduced in proportion to the reduction in aerated lung may lead to overstretch of aerated lung parenchyma and further diffuse alveolar damage. This is termed volutrauma as increased airway pressure (P_{aw}) despite low V_T, due to decreased chest wall compliance, causes minimal damage compared with high V_T, high P_{aw} ventilation.[52] Atelectrauma refers to injury due to repeated opening and closing of air spaces during tidal inflation. Both volutrauma and atelectrauma result in alveolar inflammation and elevated alveolar cytokines (biotrauma), which may 'spill' into the systemic circulation.[53] However, as CT scans performed during ARDS Network protective ventilation show that tidal inflation occurs primarily in either normally aerated or overinflated compartments, with little tidal recruitment,[54] and PET-CT scans suggest that overinflation but not tidal recruitment is inflammatory,[55] overstretch appears to be the dominant mechanism causing VILI.

OVERSTRETCH

The normal lung is fully inflated at a transpulmonary pressure of ~25–30 cmH_2O. Consequently, a maximum P_{plat}, an estimate of the elastic distending pressure, of 30 cmH_2O has been recommended.[48] However, overinflation may occur at much lower elastic distending pressures (18–26 cmH_2O).[52,56]

The transpulmonary pressure may be lower than expected for a given P_{plat} in patients with a high chest wall elastance (e.g. obesity, abdominal compartment syndrome, after abdominal or thoracic surgery). While placement of an oesophageal balloon (see Ch. 38) allows measurement of the transpulmonary pressure and may allow better titration of PEEP,[57] it must be correctly placed, have an adequate occlusion pressure ratio, and measurements are preferably performed in a semi-sitting position in order to lift the mediastinum off the oesophagus.

Finally, inspiratory muscle contraction through reduction of intrapleural pressure lowers P_{plat}, potentially avoiding simple detection of an excessive transpulmonary pressure. This is particularly common when pressure support ventilation is used as a primary mode of ventilatory support; V_T that would produce an unacceptably high P_{plat} during mechanical ventilation will produce the same volutrauma during a spontaneous or supported mode of ventilation, and should be avoided. Provided the same V_T is generated, spontaneous ventilation does not reduce VILI compared to controlled ventilation.[58]

Static or dynamic volume–pressure curves or quantitative chest CT can be used to infer overinflation, though chest CT cannot determine overstretch.[5] Consequently, unless particular expertise is available, V_T limitation is currently the most practical approach.

ADEQUATE PEEP

PEEP improves Pa_{O_2} by recruiting alveoli and increasing functional residual capacity. Because PEEP may reduce cardiac output by impairing venous return, Suter and coworkers suggested that at best PEEP the oxygen delivery (oxygen content × flow) was highest, and that this coincided with greatest compliance.[59] PEEP is commonly titrated to a particular Pa_{O_2}/Fi_{O_2} ratio such as the ARDS Network protocol.[48] However, the amount of lung available for recruitment is extremely variable,[60] and does not differ comparing pulmonary with extrapulmonary ARDS.[61] Factors such as the duration, late ARDS being less recruitable, and phenotype influence whether PEEP leads to alveolar recruitment, overinflation or a balance of both. Based on chest imaging, ARDS can be subdivided into focal, intermediate and diffuse phenotypes, with progressive increase in the amount of recruitable lung.[62,63] Applying ARDS Network ventilation to focal ARDS (about ⅓ of most cohorts) leads to high lung stress, with increased cytokine release, which can be ameliorated by using lower levels of PEEP.[64]

The lower inflection point of a volume–pressure curve has been used to set PEEP; early studies suggested that this reflected recruitment of collapsed alveoli. However, in patients with ARDS, recruitment occurs well above the lower inflection point, often along the entire volume–pressure curve and above the upper inflection point.[65,66] Concurrently, there is frequently evidence of overstretching and hyperinflation on CT scans[36,67] or dynamic volume–pressure analysis.[56] Meta-analysis of major clinical trials using protective V_T and comparing higher and lower PEEP scales[68] did not find an overall improvement in outcome with higher PEEP, although rescue therapies were required less often. However, patients with mild ARDS tended to have worse outcomes with higher PEEP, and those with moderate to severe ARDS had better outcomes.

These data suggest individual patients may benefit from a tailored approach. Although routine CT analysis has been advocated by some, it is cumbersome and has

not been shown to influence outcome; non-invasive bedside alternatives are under investigation. Consequently, PEEP titration is often a compromise aiming to minimise both atelectrauma and volutrauma.[69] Reasonable approaches to PEEP titration include: (a) the use of a scale similar to the ARDS Network protocol, (b) titration of PEEP to Pa_{O_2} aiming for a PEEP of ~15 cmH$_2$O, or (c) measuring elastic mechanics at the bedside. Consistent with Suter's early observation,[59] both nadir elastance after a recruitment manoeuvre,[70] or minimal change in driving pressure[56] (see also Ch. 38), offer bedside methods to individualise PEEP.

In patients at risk for ARDS prophylactic PEEP (8 cmH$_2$O) was not protective.[71]

Recruitment manoeuvres and open lung ventilation

Open lung ventilation refers to an approach where the lung is maximally recruited, usually through application of higher PEEP, recruitment manoeuvres, and efforts to minimise derecruitment. In theory increased lung volume will result in less tidal overinflation, and improved outcome. However, despite alveolar recruitment with open lung ventilation, overinflation may occur in previously normally aerated lung.[72] The recruitment manoeuvre may be followed by a marked improvement in oxygenation; however, this is not a consistent finding, and hypotension may occur due to reduced venous return if there is inadequate fluid loading.

During a typical recruitment manoeuvre a high level of CPAP (30–40 cmH$_2$O) is applied for 30–40 seconds in an apnoeic patient, followed by return to a lower level of PEEP and controlled ventilation. This may be suboptimal; an alternative for example is a staircase recruitment manoeuvre where airway pressure is sequentially increased every 2 minutes, and then decreased until oxygenation deteriorates.[73] A number of small trials have shown improvement in oxygenation following recruitment manoeuvres; however, the largest clinical trial[74] failed to show an effect. Grasso and colleagues[75] found that recruitment manoeuvres were effective only early in ARDS and with lower levels of baseline PEEP, which probably explains the variable responses reported.

In addition to physical recruitment of alveoli, lung stretch above resting V_T is the most powerful physiological stimulus for release of pulmonary surfactant from type II cells. This is associated with a decrease in lung elastance and improved Pa_{O_2} in the isolated perfused lung,[76] and is a possible explanation for the improvement in oxygenation, recruited lung volume and elastance reported with addition of three sigh breaths in patients with ARDS.[77] Similarly, in models of lung injury biologically variable or fractal V_T is associated with less lung damage with lower alveolar levels of IL-8,[78] improved oxygenation and lung elastance, and greater surfactant release.[79] These data caution against monotonous low V_T ventilation, and suggest that intermittent or variable lung stretch may reduce lung injury.

MODE OF VENTILATION

Non-invasive ventilation should not be routinely used in ARDS (see Ch. 37) and most patients require intubated mechanical ventilation. Following intubation, controlled ventilation allows immediate reduction in the work of breathing, and application of PEEP and a controlled Fi_{O_2}. Later in the clinical course assisted or supported modes of ventilation may allow better patient–ventilator interaction (see Ch. 31), and possibly improved oxygenation through better $\dot{V}/\dot{Q}$ mismatch as a result of diaphragmatic contraction.[80] Withdrawal or weaning from mechanical ventilation is discussed in Chapter 31.

An advantage of assist-control ventilation (as used in the ARDS Network study) is that spontaneous effort generates a controlled V_T. Care should be taken with synchronised intermittent mandatory ventilation (SIMV), particularly if pressure support is added to SIMV, as excessive V_T may occur during supported breaths. There is an increasing tendency to use pressure-controlled ventilation (PC) or pressure-regulated volume control (PRVC) as P_{pk} is lower than volume-controlled (VC) ventilation with a constant inspiratory flow pattern. However, the decelerating flow pattern of PC or PRVC means that most of the resistive pressure (P_{res}) during inspiration is dissipated by end inspiration, which is in contrast to VC with a constant inspiratory flow pattern where P_{res} is dissipated at end inspiration (see Fig. 31.2). Consequently, with PC and PRVC $P_{pk} \approx P_{plat}$ which is the same as P_{plat} during VC.[81] Both oxygenation, haemodynamic stability and mean airway pressure are no different between PC and VC, and a moderate-sized randomised study found no difference in outcome.[82] However, there may be differences in lung stress due to greater viscoelastic build-up with VC.[83]

Inverse ratio ventilation, often together with PC, has been used in ARDS. However, when PEEP$_i$ and total PEEP are taken into account, apart from a small decrease in Pa_{O_2}, there are no advantages with inverse ratio ventilation. Mean airway pressure is higher with a greater risk of both haemodynamic consequences, and regional hyperinflation.[81] Consequently, an inspiratory to expiratory ratio greater than 1:1 is recommended.

A number of other modes of ventilation (see Ch. 31) including airway pressure release ventilation (APRV) and high-frequency oscillation (HFO) have been proposed for use in ARDS. Randomised clinical trials have not shown improved outcomes with APRV,[84] despite potential physiological benefits. The small V_T used with HFO are appealing, and some centres use HFO as rescue therapy when conventional ventilatory strategies are failing, while others would consider veno-venous extracorporeal membrane oxygenation (ECMO; see Ch. 41). Definitive clinical trials of both trials are underway and awaited.

TARGET BLOOD GASES

As discussed above there are many variables that need to be considered when choosing target blood gases in ARDS. For example if a patient also has a traumatic brain injury, it may be inappropriate to accept hypercapnia.

Oxygenation targets and Fi_{O_2}

There must be a compromise between the major determinants of oxygenation including the extent of poorly or non-aerated lung, hypoxic pulmonary vasoconstriction and mixed venous oxygen saturation, and the target Pa_{O_2}. The association between cognitive impairment and arterial saturation (Sa_{O_2}) <90%[14] suggests that a $Sa_{O_2} \geq 90\%$, usually a $Pa_{O_2} > 60$ mmHg, is a reasonable target. Because positive-pressure ventilation may reduce cardiac output it is also important to consider tissue oxygenation.

In addition to PEEP, increased Fi_{O_2} is used to improve Sa_{O_2}. However, high Fi_{O_2} may also cause tissue injury including diffuse alveolar damage. The balance between increased airway pressure and Fi_{O_2} is unknown, but high Fi_{O_2} is generally regarded as being less damaging.[85] In part this is because diffuse alveolar damage itself protects the lung against hyperoxia, perhaps through prior induction of scavengers for reactive oxygen species.[86] A reasonable compromise is to start ventilation at a Fi_{O_2} of 1 and to titrate down, aiming for a $Fi_{O_2} \leq 0.6$. In patients with extreme hypoxaemia, additional measures such as inhaled nitric oxide (iNO) and prone positioning may be tried, along with a lower Sa_{O_2} target.

Carbon dioxide target

Low V_T strategies will result in elevations in Pa_{CO_2} unless minute ventilation is augmented by an increase in respiratory rate. The ARDS Network protocol aimed at normocapnia, with a maximum respiratory rate of 35, to minimise respiratory acidosis.[48] This exposes the lung to more repeated tidal stretch, and may result in dynamic hyperinflation due to a shortened expiratory time.[87] In addition, allowing the Pa_{CO_2} to rise above normal may not be harmful in many patients.

If hypercapnic acidosis occurs slowly, intracellular acidosis is well compensated, and the associated increase in sympathetic tone may augment cardiac output and blood pressure. Although the respiratory acidosis may worsen pulmonary hypertension and induce myocardial arrhythmias these effects are often small, particularly if there has been time for metabolic compensation. In addition, in an ischaemia–reperfusion model of ARDS, therapeutic hypercapnia reduced lung injury and apoptosis.[88] However, clinical studies of permissive hypercapnia must be undertaken before therapeutic hypercapnia is considered. Hypercapnia should be avoided in patients with or at risk from raised intracranial pressure.

ADDITIONAL MEASURES TO IMPROVE OXYGENATION

PRONE POSTURE

In ~70% of patients with ARDS, prone positioning will result in a significant increase in Pa_{O_2}, with a modest increase in Pa_{O_2} sustained in the supine position.[89] The mechanisms involved include recruitment of dorsal lung, with concurrent ventral collapse; however, perfusion is more evenly distributed leading to better $\dot{V}/\dot{Q}$ matching. Recent meta-analysis[90] did not show an improvement in overall mortality; however, when studies only enrolling patients with moderate and severe ARDS were examined, prone position was associated with reduced ICU mortality without increased airway complications. Meta-regression revealed a trend to better results with longer periods of prone position. These data support the use of prone positioning as rescue therapy in life-threatening hypoxaemia.

MANIPULATION OF THE PULMONARY CIRCULATION

Inhaled nitric oxide (iNO) and aerosolised prostacyclin (PGI_2) may be used to reduce pulmonary shunt and right ventricular afterload by reducing pulmonary artery impedance. When hypoxic pulmonary vasoconstriction is active, there is redistribution of pulmonary blood flow away from the poorly ventilated dependent areas to more normally ventilated lung leading to an increase in Pa_{O_2}. Both iNO and PGI_2 are delivered to well-ventilated lung; both vasodilate the local pulmonary circulation and augment the effects of hypoxic pulmonary vasoconstriction. Intravenous almitrine is a selective pulmonary vasoconstrictor that reinforces hypoxic pulmonary vasoconstriction and, although this may improve oxygenation alone, there is a synergistic effect with iNO.

Inhaled NO or PGI_2 may also be used to reduce right ventricular afterload; however, a consequent increase in cardiac output is rare in ARDS. Intravenous PGI_2 will improve cardiac output in ARDS, though there is non-specific pulmonary vasodilation with increased blood flow through poorly ventilated lung zones, resulting in deterioration in oxygenation.

Inhaled nitric oxide

Nitric oxide is an endothelium-derived smooth muscle relaxant. It also has other important physiological roles including neurotransmission, host defence, platelet aggregation leucocyte adhesion, and bronchodilation. Doses as low as 60 parts per billion iNO may improve oxygenation, however, commonly used doses in ARDS are 1–60 parts per million, with the higher doses required for reduction in pulmonary artery pressure. A rise in Pa_{O_2} exceeding 20% is generally regarded as a positive response; iNO should be continued at the minimum effective dose.

Inhaled NO may be delivered continuously or using intermittent inspiratory injection. Delivery is usually in the form of medical grade NO/N_2, and this should be adequately mixed to avoid delivery of variable NO

concentrations. It is recommended that inspiratory NO and NO_2 concentrations are measured, either by an electrochemical method or by chemiluminescence. The electrochemical method is accurate to 1 p.p.m., which is adequate for clinical use, and is less expensive. Local environmental levels of NO and NO_2 are low and predominantly influenced by atmospheric concentrations; however, it is still common practice to scavenge expired gas. Binding to haemoglobin in the pulmonary circulation rapidly inactivates NO, and systemic effects are reported only following high concentrations of iNO. Systemic methaemoglobin levels may be monitored, and are generally less than 5% during clinical use of iNO, but they should be compared with a baseline level. Nitric oxide may cause lung toxicity through combination with oxygen free radicals, and through metabolism of NO to NO_2; however, these do not appear to be major clinical problems.

Only 40–70% of patients with ARDS have improved oxygenation with iNO (responders), and this is likely due to active hypoxic pulmonary vasoconstriction in the remainder. Addition of i.v. almitrine can have an additive effect on oxygenation, and may improve the number of responders. Clinical trials[91] have shown no improvement in mortality or reversal of ARDS, and an increased risk of renal impairment. However, iNO transiently improves oxygenation (as compared with placebo or no iNO), which has been sustained beyond 12–24 hours in some trials. As constant dosing of iNO leads to both increased sensitivity and apparent tachyphylaxis,[92] subsequent investigation needs to consider different dose regimens. Currently iNO cannot be recommended for routine use in ARDS; however, in some patients with severe hypoxaemia, perhaps in combination with almitrine, iNO will provide temporary rescue.

Inhaled prostacyclin

PGI_2 (up to 50 ng/kg/min) improves oxygenation as effectively as iNO in ARDS patients,[93] and may reduce pulmonary hypertension. It is continuously jet nebulised due to its short half-life (2–3 minutes). Potential advantages include increased surfactant release from stretched type II cells, avoidance of the potential complications of iNO, and minimal toxicity. However, PGI_2 is dissolved in an alkaline glycine buffer, which alone can result in airway inflammation, and the sticky nature of the aerosol can result in expiratory valve obstruction. Iloprost is a derivative of PGI_2 with similar activity, a longer duration of action, without an alkaline buffer. Neither agent has been shown to improve outcome in ARDS patients.

PHARMACOLOGICAL THERAPY

There is no proven pharmacological therapy for ARDS despite numerous studies. However, the lack of a protective ventilation strategy in many of these studies may have masked a drug effect.

SURFACTANT REPLACEMENT THERAPY

Surfactant dysfunction is an important and early abnormality contributing to lung damage in ARDS.[19,94] Pulmonary surfactant reduces surface tension promoting alveolar stability, reducing work of breathing and lung water. In addition surfactant has important roles in lung host defence. Reactive oxygen species, phospholipases and increased protein permeability lead to inhibition of surfactant function. In addition, composition is abnormal, and turnover markedly increased. Ventilator-induced lung injury is difficult to demonstrate without surfactant dysfunction.[94] Consequently, there has been considerable interest in exogenous surfactant replacement therapy.

Exogenous surfactant therapy has an established role in neonatal respiratory distress syndrome. In paediatric ARDS, particularly that due to direct lung injury, clinical trials have been promising. However, in adults results have been disappointing; subgroup analysis of recombinant surfactant protein-C-based surfactant administered intratracheally improved oxygenation in direct ARDS without an improvement in mortality.[95] However, subsequent research in this cohort failed to confirm these data, perhaps owing to inactivation of the surfactant during administration.[96]

GLUCOCORTICOIDS

Glucocorticoids may have a role in ARDS through their reduction of the intense inflammatory response and their potential to reduce fibroproliferation and collagen deposition, by faster degradation of fibroblast procollagen mRNA. Preventative steroids increase the incidence of ARDS and, although there may be a greater number of ventilator-free days and the possibility of a reduction in mortality,[97,98] neuromuscular complications, and increased mortality when steroids are administered more than 13 days after the onset of ARDS,[99] argue against their routine use.

KETOCONAZOLE

Ketoconazole is an antifungal drug that also inhibits thromboxane synthase and 5-lipo-oxygenase. However, promising results from small studies in at-risk patients have not been confirmed in a larger treatment trial.[100]

OTHER PHARMACOLOGICAL THERAPIES

Numerous other therapies including cytokine antagonism, non-steroidal anti-inflammatory drugs, scavengers of reactive oxygen species, and lisofylline[101] have been trialled without success. The complex balance of inflammation and repair in ARDS, and the critical additional damage secondary to VILI, may explain these results. However, studies in less heterogeneous groups with minimisation of VILI using standardised ventilation protocols, together with a growing understanding of ARDS, offer potential pharmacological therapies.

Pulmonary embolism

Andrew R Davies and David V Pilcher

Pulmonary embolism (PE) is a commonly considered but relatively uncommonly diagnosed condition in hospitalised patients. It is important to have an adequate understanding of the pathophysiology as well as a rapid and reliable strategy of investigation and management. This is particularly important in intensive care unit (ICU) patients where diagnosis can be difficult and PE may be life threatening, with mortality rates in haemodynamically unstable patients being about 30%.[1]

Early deaths in PE are usually the result of acute right ventricular (RV) failure and cardiogenic shock. After the first few days, mortality is less common and mostly determined by recurrent thromboembolic events and the underlying disease state.

AETIOLOGY

Deep venous thrombosis (DVT) and PE are components of a single disease termed venous thromboembolism (VTE). Embolisation of DVT to the pulmonary arteries leads to PE. The incidence of VTE in the population is about 1 in 1000 per year and is more common both with advancing age and in males.

Most PE results from DVT of the lower limbs, pelvic veins or inferior vena cava (IVC), although DVT of the upper limbs, right atrium or ventricle does occur. Up to 40% of patients with DVT develop PE, although if the DVT is isolated to below the knee then clinically obvious PE is rare.

Predisposing risk factors for VTE involve one or more components of Virchow's triad: (1) venous stasis, (2) vein wall injury, and (3) hypercoagulability of blood. The main factors are immobility (from any cause), surgery, trauma, malignancy, pregnancy and thrombophilia (see **Box 34.1**).

VTE can be recurrent, which should prompt investigation for thrombophilia. This is a group of inherited conditions associated with a high incidence of VTE. The most important of these is activated protein C resistance, which is mediated by the factor V Leiden mutation. Up to 50% of patients with recurrent VTE episodes (as well as 20% of patients with a single episode) have this condition; however, its association appears to be greater with DVT than with PE.[2] Up to 5% of patients with VTE develop chronic pulmonary hypertension.[3]

PATHOPHYSIOLOGY

The effects of PE range from being incidental and clinically irrelevant to causing severe obstruction to the pulmonary circulation and sudden death. Pulmonary arterial obstruction and the subsequent release of vasoactive substances such as serotonin and thromboxane A_2 from platelets lead to elevated pulmonary vascular resistance and acute pulmonary hypertension.

Acute pulmonary hypertension increases RV afterload and RV wall tension, which leads to RV dilatation and dysfunction, with coronary ischaemia being a major contributing mechanism.[4] In massive PE, the combination of coronary ischaemia, RV systolic failure, paradoxical interventricular septal shift and pericardial constraint leads to left ventricular (LV) dysfunction and obstructive shock. In patients with underlying cardiorespiratory disease, a small PE can have profound consequences.

Pulmonary arterial obstruction causes a mismatch between lung ventilation and perfusion, which leads to hypoxaemia. The ventilation of lung units that have reduced or no perfusion causes increased dead-space ventilation and an increase in the end-tidal to arterial CO_2 gradient. Alveolar hyperventilation also occurs, leading to hypocapnia. Increased right atrial pressure can open a patent foramen ovale, which may result in right-to-left shunting, manifested as either refractory hypoxaemia or paradoxical (arterial) embolisation, commonly to the brain, leading to cerebral infarction.

CLINICAL PRESENTATION

PE is relatively uncommon in critically ill patients despite the frequent presence of risk factors for VTE. However, when PE does occur the diagnosis is frequently overlooked or is difficult to confirm because several more prevalent cardiopulmonary diseases, including heart failure, pneumonia and chronic lung diseases, have similar clinical features. Up to one in six patients have the diagnosis made more than 10 days after symptom onset.[5]

Clinical assessment should raise the suspicion of PE but is neither sensitive nor specific enough to reliably confirm or exclude the diagnosis on its own. A number of clinical decision rule (CDR) systems have been

Box 34.1 Risk factors for venous thromboembolism

Heart failure
Increasing age

developed, the most widely reported of which are the Wells' score and the Geneva score.[6] These CDRs use a combination of symptoms, signs and risk factors to stratify patients into different disease probability categories. CDRs provide accurate and reproducible determinations of probability and outcome for use in a diagnostic or therapeutic strategy. Patients can therefore have their probability determined as unlikely (in whom PE can be safely ruled out with a negative D-dimer result)[7] or likely (in whom an imaging test is required and in whom prompt anticoagulant therapy should be considered). The differential diagnoses are listed in **Box 34.2**.

SYMPTOMS

Dyspnoea, pleuritic chest pain, and haemoptysis are the classic symptoms of PE. Most patients will have at least one of these symptoms, with dyspnoea being the most common. The combination of pleuritic chest pain and haemoptysis reflects a late presentation where pulmonary infarction has occurred. If syncope occurs, and there is no other obvious cause, it is likely that this is a massive PE. A family history of venous thrombosis makes an inherited thrombophilia likely.

PHYSICAL SIGNS

Physical signs can be absent, but the most frequent sign is tachypnoea. Others include tachycardia, fever and signs of RV dysfunction (raised jugular venous pressure, parasternal heave and loud pulmonary

component of the second heart sound). In massive PE, signs may include hypotension, pale mottled skin and peripheral or even central cyanosis. It is important to examine for signs of DVT, particularly in the legs.

INVESTIGATIONS

The diagnosis of PE requires a high level of clinical suspicion and the appropriate use of investigations. The aim of these investigations is to confirm or exclude the presence of PE, but also to stratify treatment accordingly. The optimal investigation strategy depends upon the individual patient and institution; however, multidetector computed tomographic pulmonary angiography (CTPA) scanning is now the imaging test of first choice. A suggested investigation algorithm is shown in **Figure 34.1**.

D-DIMER

The serum D-dimer level, which becomes elevated when acute thrombus formation occurs, is useful for exclusion of VTE, particularly when it is normal and combined with a low-risk clinical assessment.[8] Because of its sensitivity, negative D-dimer tests, particularly using enzyme-linked immunosorbent assays (ELISA), enzyme-linked immunofluorescence assays (ELFA) and latex quantitative assays, are highly predictive of the absence of both DVT and PE.

A high D-dimer concentration is also an independent predictive factor associated with mortality.[9] Unfortunately, D-dimer levels are often elevated in ICU patients for reasons including infection, inflammation, cancer, surgery and trauma, acute coronary syndrome, stroke, peripheral artery disease or ruptured aneurysm. D-dimer tests should be used with caution in patients who are elderly (as the upper limit of normal increases with age), who have prolonged symptoms and who are already receiving therapeutic anticoagulant therapy.

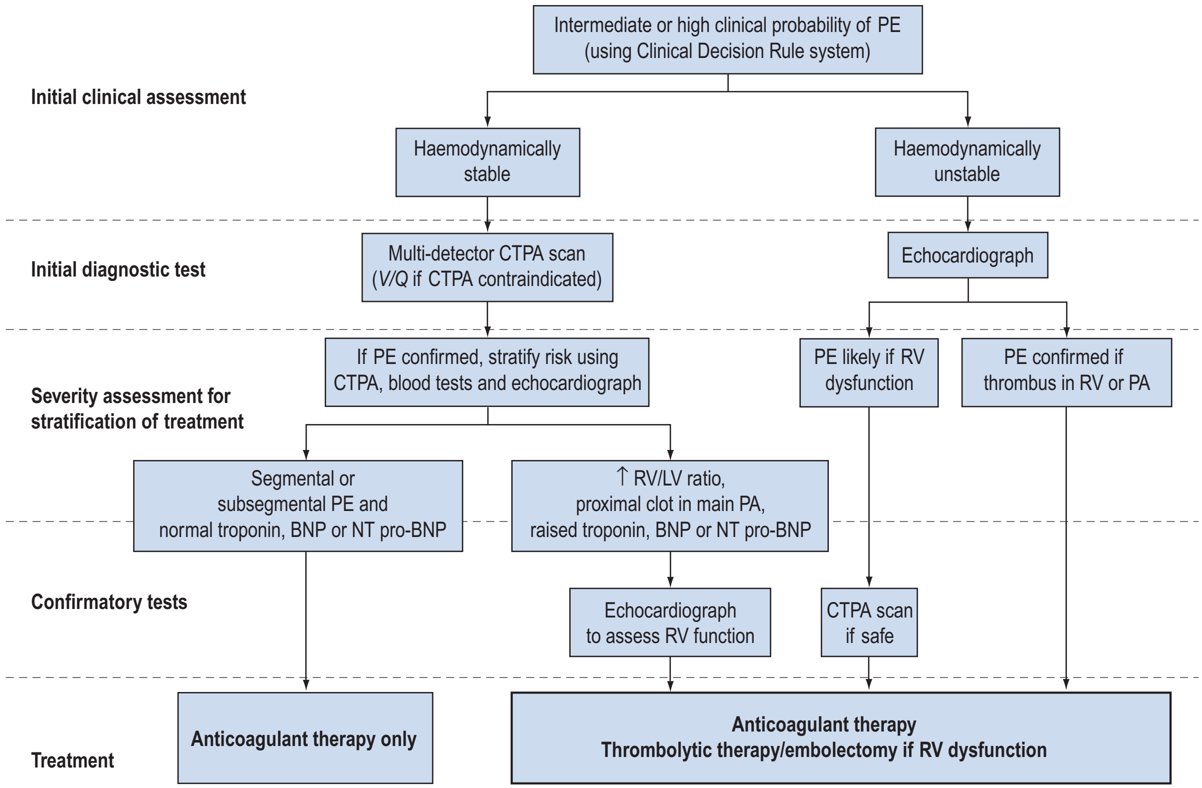

Figure 34.1 Suggested investigation and treatment algorithm for pulmonary embolism (PE). CTPA=computed tomographic pulmonary angiography; *V/Q*=ventilation/perfusion scan; RV=right ventricular; PA=pulmonary artery; BNP=brain natriuretic peptide; RV/LV=right ventricle/left ventricle; IVC=inferior vena cava.

TROPONIN, BRAIN NATRIURETIC PEPTIDE (BNP) AND NT-TERMINAL PRO-BNP

Although of little use for confirming or excluding the diagnosis, measurement of troponin, BNP or NT-pro-BNP can assist in risk stratification of patients with diagnosed PE. A raised troponin is associated with haemodynamic instability in patients with non-massive PE independently of clinical, echocardiographic and laboratory findings.[10] Raised troponin also predicts a higher mortality.[11] Low levels of BNP and NT-pro-BNP have been shown to correlate with an uneventful course in patients with known PE.[12] NT-pro-BNP appears to be a better predictor of outcome than troponin.[13]

ARTERIAL BLOOD GASES

A normal arterial blood gas profile does not exclude the diagnosis of PE; however, hypoxaemia (with a widened alveolar–arterial oxygen gradient), hypocapnia and an increased end-tidal CO_2 gradient should raise the suspicion of PE, even if these are common findings in critically ill patients for other reasons. Metabolic acidosis may be present if shock from a large PE occurs.

ELECTROCARDIOGRAPH

A normal electrocardiograph (ECG) is found in about one-third of patients. Apart from sinus tachycardia (which is non-specific), the most frequent ECG abnormalities are non-specific S–T depression and T-wave inversion in the anterior leads, reflecting right heart strain. The pattern of a deep S-wave in lead I and a Q-wave and inverted T-wave in lead III (S1Q3T3) is classical, but infrequently present. Other possible ECG abnormalities include left- or right-axis deviation, P pulmonale, right bundle-branch block and atrial arrhythmias. The ECG is also useful in excluding acute myocardial infarction and pericarditis.

CHEST X-RAY

The chest X-ray is often normal or only slightly abnormal, with non-specific signs such as cardiac enlargement, pleural effusion, elevated hemidiaphragm, atelectasis and localised infiltrates. More specific findings, including focal oligaemia, a peripheral wedge-shaped density above the diaphragm and an enlarged right descending pulmonary artery, are uncommon and difficult for non-radiologists to identify. The chest

X-ray is also useful in identifying an alternative diagnosis such as pneumothorax, pneumonia, acute pulmonary oedema, rib fracture and pleural effusion.

IMAGING TESTS INCLUDING CTPA SCAN

Imaging is required in any patient with a high or likely clinical probability. As the technology has improved, CTPA scanning, especially the multidetector scanner (MD-CTPA),[14] has now largely replaced lung ventilation–perfusion (V/Q) scanning as the cost-effective and clinically reliable imaging procedure of choice in patients with suspected PE.[15] This is because the CTPA scan has the advantages of greater diagnostic accuracy, ready availability at most hospitals, more rapid image acquisition time, and the possibility of making an alternative diagnosis. High-resolution images to the level of segmental and in some cases subsegmental pulmonary arteries can be obtained in a short time period (often a single breath-hold). When compared with conventional angiography it appears reliable, with excellent sensitivity, specificity and accuracy.[16] It is therefore recommended that the CTPA scan should be the principal imaging test for patients with high and moderate probability of PE.

Although inconclusive CTPA scans occur in around 10%, a negative CTPA result means that withholding anticoagulant therapy is safe.[17] An emerging problem of CTPA scanning, however, is the increased detection (around 10%) of small peripheral emboli in subsegmental pulmonary arteries due to better visualisation of these arteries. The clinical significance of these findings in critically ill patients is unknown; however, these are usually unlikely to lead to a bad outcome if left untreated.

The CTPA scan can also be used to assess the severity of PE. An increased RV/LV ratio[18] and clot in the proximal branches of the pulmonary artery[19] correlate with the clinical severity of PE. Severity stratification is further increased by combining CTPA scanning with other tests such as troponin[10] and BNP or NT-Pro-BNP.[12] CTPA scanning may also identify the causative DVT in the veins of the legs, pelvis and abdomen or detect alternative or additional diagnoses such as a pulmonary mass, pneumonia, emphysema, pneumothorax, pleural effusion or mediastinal adenopathy (**Fig. 34.2**).

Despite the increased use of the CTPA scan, the V/Q scan retains a role when CTPA is either unavailable or contraindicated (e.g. significant renal

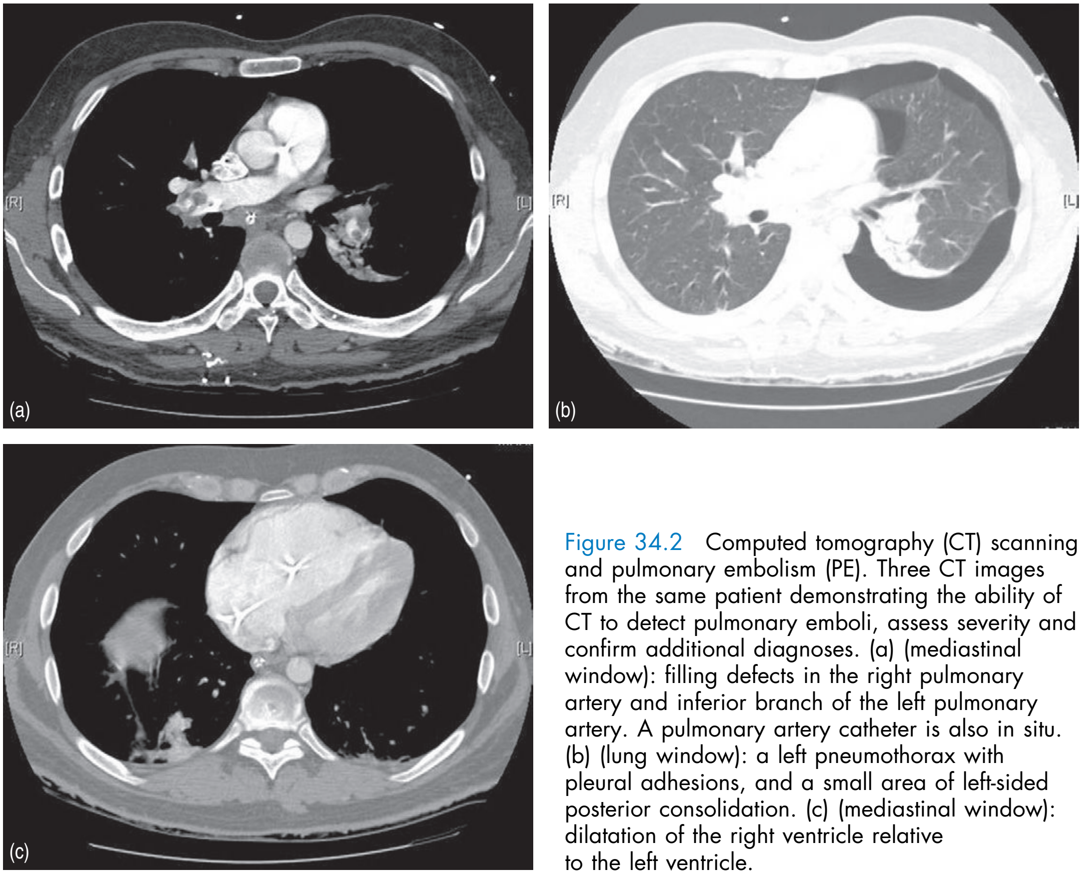

Figure 34.2 Computed tomography (CT) scanning and pulmonary embolism (PE). Three CT images from the same patient demonstrating the ability of CT to detect pulmonary emboli, assess severity and confirm additional diagnoses. (a) (mediastinal window): filling defects in the right pulmonary artery and inferior branch of the left pulmonary artery. A pulmonary artery catheter is also in situ. (b) (lung window): a left pneumothorax with pleural adhesions, and a small area of left-sided posterior consolidation. (c) (mediastinal window): dilatation of the right ventricle relative to the left ventricle.

impairment, anaphylaxis to intravenous contrast or pregnancy).[20] V/Q scanning also allows quantification of regional blood flow within the lungs, which may be required in the assessment of chronic pulmonary venous embolism.

PE may also be diagnosed by gadolinium-enhanced magnetic resonance pulmonary angiography (MRA). In some series as many as 25% of examinations have been regarded as non-interpretable.[21]

ECHOCARDIOGRAPHY

Because of its portability, echocardiography has the greatest usefulness in critically ill patients with probable PE. Many patients with PE have an echocardiographic abnormality, the most common being RV dilatation, RV hypokinesis, paradoxical interventricular septal motion toward the LV, tricuspid regurgitation and pulmonary hypertension. The pattern of RV hypokinesis with apical sparing is considered pathognomonic for PE.[22] The presence of RV dysfunction correlates with mortality.[23] However, it must be noted that a negative echocardiography does not exclude PE.

Transthoracic echocardiography will also allow estimation of pulmonary arterial pressure, identification of intracardiac thrombi (which usually requires surgical embolectomy) and aids in differential diagnosis by excluding aortic dissection and pericardial tamponade. Transoesophageal echocardiography has the additional benefit of directly identifying embolus in the proximal pulmonary arteries, which is common in patients with haemodynamically significant PE.

Echocardiography has its best application in haemodynamically unstable patients, where it can be rapidly brought to the patient. If the patient has RV dilatation and hypokinesis in the right clinical setting, PE is extremely likely.

DIAGNOSIS OF DVT USING ULTRASOUND

Doppler ultrasound has been recommended to search for DVT in the leg veins, from where over 90% of emboli originate. If a leg DVT is confirmed, anticoagulation is required unless the DVT is entirely below the knee, where the associated morbidity is low. Ultrasound is highly accurate in symptomatic or proximal DVT, although in asymptomatic patients ultrasound is much less likely to find DVT, meaning the absence of a DVT does not exclude PE. The best use of ultrasound is when a CTPA scan is contraindicated.[24]

INVESTIGATION STRATEGY IN HAEMODYNAMICALLY STABLE PATIENTS

- A CTPA scan is the preferred initial test and, if positive, the patient should be stratified into high or moderate risk. The presence of clot within pulmonary arteries confirms the diagnosis of PE.
- An echocardiograph should then be considered to assess RV dysfunction for high-risk patients who have:
  - clot within proximal pulmonary arteries
  - raised RV/LV ratio (i.e. >0.9–1.0)
  - raised troponin, BNP or NT-pro-BNP.
- If a CTPA scan is not possible (contraindicated or unavailable), an alternative investigation, such as a V/Q scan, MRA or ultrasound should be considered.
- None of these tests excludes PE, but a negative result in a haemodynamically stable patient means that the outcome without anticoagulation is unlikely to be poor.

INVESTIGATION STRATEGY IN HAEMODYNAMICALLY UNSTABLE PATIENTS

- An echocardiograph (preferably transoesophageal) should be the first test performed.
- If the patient has acute RV dilatation and visible embolus, PE is confirmed.
- If there is RV dilatation but no visible embolus, then a CTPA scan is required depending on how unstable the patient is.
- If there is no RV dilatation, the haemodynamic instability is unlikely to be due to PE (although this cannot be excluded completely). Efforts towards finding an alternative diagnosis are the priority.
- If echocardiography is not readily available, a CTPA scan should be performed.

MANAGEMENT

MANAGEMENT PRINCIPLES

Once PE has been confirmed patients at all levels of severity should receive anticoagulation with either unfractionated or low-molecular-weight heparin (LMWH) to prevent further embolisation. In more severe cases of PE, however, the key principle is embolus destruction to maximise a more rapid effect on relief of RV dysfunction. To assist in planning management, it is important to grade the severity of PE. Prediction models based on clinical findings at diagnosis may be useful for the prognostic assessment of patients with acute PE. The Pulmonary Embolism Severity Index is the most extensively validated prognostic clinical score[25] and a simplified version of this has been recently developed.[26] The place of these in critical illness is yet to be determined and it may be that a combination of a predictive scoring system with a diagnostic test is the most useful.[27]

MASSIVE PE (HAEMODYNAMICALLY UNSTABLE)

Patients with PE and hypotension have an approximately 30% mortality rate despite treatment.[1] If cardiopulmonary resuscitation is required, this increases to

65%. These patients have the most to benefit from a strategy that includes attempts at urgent embolus destruction (with thrombolytic therapy or embolectomy), concurrent haemodynamic support and prevention of further embolisation.

SUBMASSIVE PE (HAEMODYNAMICALLY UNSTABLE WITH EVIDENCE OF RV DYSFUNCTION)

Patients with PE and evidence of RV dysfunction have higher mortality (around 15%) and recurrence rates than those with normal RV function.[23] They also develop shock and RV thrombi more frequently. These patients require prevention of further embolisation but also warrant strong consideration of embolus destruction using thrombolytic therapy. Thrombolytic drugs appear to improve outcomes,[28] although this appears to be at the expense of a higher bleeding risk.[29] The presence of RV dysfunction (to meet the submassive classification) can be confirmed using echocardiogram but can also be inferred from evidence of RV dilatation on CTPA scanning or by raised troponin, BNP and NT-pro-BNP, all of which have been shown to predict higher mortality.[30]

MILD PE (HAEMODYNAMICALLY STABLE WITH NO RV DYSFUNCTION)

Patients with PE who have normal blood pressure and normal RV function (determined by echocardiography or CTPA scan) have a low risk of death or recurrence. The predominant management goal is prevention of further embolisation using anticoagulant therapy, as treatment focused on embolus destruction is unlikely to confer additional benefits.

In summary, the major principles of management are therefore:

- prevention of further embolisation (for all of massive, submassive and mild PE)
- embolus destruction (for massive and submassive PE)
- concurrent haemodynamic support (only required in massive PE).

A suggested management strategy is outlined in Figure 34.1.

PREVENTION OF FURTHER EMBOLISATION

ANTICOAGULANT THERAPY

Heparin has been known to prevent recurrence and reduce the mortality from PE for over 40 years. LMWHs are as effective and safe as unfractionated heparin[31] and may even be better.[32] LMWHs offer several advantages over unfractionated heparin, including a longer half-life, increased bioavailability, a more predictable dose–response and fewer requirements for monitoring and dose adjustments. They should be readily used in the stable patient with PE.

Table 34.1 Weight-based dosing of intravenous heparin

INITIAL DOSING			
Loading 80 units/kg			
Maintenance infusion 18 units/kg per hour			
Perform APTT in 6 hours			
SUBSEQUENT DOSE ADJUSTMENTS			
APTT	DOSE CHANGE (UNITS/KG PER HOUR)	ADDITIONAL ACTION	NEXT APTT
<35 seconds	+4	Rebolus of 80 units/kg	6 hours
35–45 seconds	+2	Rebolus of 40 units/kg	6 hours
46–70 seconds	Nil	Nothing	6 hours
71–90 seconds	–2	Nothing	6 hours
>90 seconds	–3	Stop infusion for 1 hour	6 hours

Adapted from Raschke et al.[33]
APTT=activated partial thromboplastin time.

Unfractionated heparin should be used in patients with renal impairment, and following thrombolytic therapy or embolectomy, as it can be easily and rapidly reversed. Intravenous unfractionated heparin should be administered after a bolus and initial monitoring should be with 6-hourly activated partial thromboplastin time (APTT) testing. Since subtherapeutic levels of anticoagulant therapy increase the risk of recurrence, it is important to achieve therapeutic heparinisation rapidly. Weight-based dosing of heparin should be used as target anticoagulation levels are reached sooner[33] (**Table 34.1**).

The predominant complications of both unfractionated heparin and LMWHs are bleeding related. These include bleeding peptic ulcer, stroke, retroperitoneal haematoma and postsurgical wound haemorrhage. Heparin-induced thrombotic thrombocytopenia syndrome (HITTS) can also occur. Bleeding complications and HITTS appear to be less common when LMWHs are being used. A number of conditions are considered to be relative contraindications to anticoagulant therapy. These include active peptic ulceration, recent surgery, recent trauma and recent cerebral haemorrhage. In each individual patient the risk-to-benefit ratio (taking into account the severity of the PE) should be considered before anticoagulation is withheld from the patient.

Oral anticoagulants should be started as soon as possible so that LMWH or unfractionated heparin can eventually be ceased. For warfarin, this is generally when the international normalised ratio is >2.0. Although warfarin has been commonly used as the long-standing anticoagulant of choice, adverse events

leading to hospitalisation remain common.[34] New oral anticoagulants, including rivaroxaban (which competitively binds activated factor X) and dabigatran (a direct inhibitor of thrombin) have been developed.[35,36] These drugs have more rapid onset of action and more predictable anticoagulant effects meaning fixed dosages and no routine laboratory coagulation monitoring. Large studies have found that rivaroxaban is non-inferior to a LMWH/warfarin combination[37] and dabigatran is non-inferior to warfarin.[38] The place of these drugs in critically ill patients with PE remains unknown.

INFERIOR VENA CAVA FILTER

Inferior vena caval (IVC) filters are another method used to prevent further embolisation. They may also be useful as primary prevention, although safety and efficacy have not been firmly established. IVC filters are indicated for patients in whom anticoagulation is contraindicated and those who experience recurrent PE despite adequate anticoagulation.[39] They may have a role in patients with massive or submassive PE who have undergone open surgical embolectomy or thrombolysis. Insertion is usually performed percutaneously in a radiology department, but it can be done at the bedside. They lower early recurrence rates but increase long-term DVT recurrence rates.[40] Newer retrievable designs may be more efficacious and more safe if removed at the appropriate time.

Absolute indications include:

- new or recurrent PE despite anticoagulation
- contraindications to anticoagulation
- complications resulting from anticoagulation.

Other recommended indications include:

- patients with extensive DVT
- patients following a surgical embolectomy
- patients following thrombolytic therapy.

EMBOLUS DESTRUCTION

THROMBOLYTIC THERAPY

Intravenous thrombolytic drugs result in dramatic and immediate haemodynamic improvement in some patients by dissolving the embolus and rapidly reducing pulmonary arterial obstruction. Experimental studies, clinical observations and randomised trials have consistently demonstrated the favourable effects of thrombolytic therapy on angiographic, haemodynamic and scintigraphic parameters of patients with acute PE, although comparisons with patients who received heparin have essentially revealed similar degrees of embolus resolution after a few days to a week.

A large multicentre patient registry found that patients receiving thrombolytic therapy (clearly on an ad hoc basis) for PE had lower rates of mortality and recurrence than patients receiving heparin.[41] Despite this, no randomised study has demonstrated that thrombolytic therapy improves survival over standard anticoagulation, most likely because studies have been underpowered. A meta-analysis found that thrombolytic therapy for PE was associated with a non-significant reduction in recurrent PE or death when compared with heparin.[29] A significant survival benefit in favour of thrombolytic therapy was demonstrable when analysis was restricted to those studies that included massive PE.

It is therefore recommended that once the diagnosis has been confirmed thrombolytic therapy should be given without delay to patients with massive PE unless there is a clear contraindication.[42] Around 90% of patients should respond to thrombolytic therapy.[43] The clinical benefits and relative underuse of this therapy have been recently highlighted using non-randomised data.[44]

There is also justification for the use of thrombolytic therapy in patients with submassive PE as a randomised study found a significant reduction in the requirement for emergency escalation of treatment, although without an effect on survival.[28] It would also seem appropriate to give thrombolytic therapy to patients with demonstrable intracardiac thrombus.

There is a large array of thrombolytic drugs with few comparative studies. Although there may be slight differences between thrombolytic drugs, the choice of drug is less important than the choice to give thrombolytic therapy at all. Suggested doses are recommended in **Table 34.2**, and this can be administered through either a peripheral or a central venous catheter. In contrast to acute myocardial infarction, thrombolytic therapy may be useful in PE when given up to 14 days after symptoms begin.[45] Once the thrombolytic therapy has been administered, heparin should be commenced.

Haemorrhagic complications are not uncommon and can significantly affect patient morbidity; however it is difficult to predict those patients who are at the highest risk for bleeding. Major clinically significant bleeding can occur in up to 10% of patients, although cerebral haemorrhage is fortunately uncommon

Table 34.2 Recommended doses of thrombolytic drugs for pulmonary embolism

Urokinase	4400 units/kg bolus (over 10 minutes) followed by 4400 units/kg per hour for 12 hours
Streptokinase	250000 unit bolus (over 15 minutes) followed by 100000 units/hour for 24 hours
Alteplase	10 mg bolus followed by 90 mg over 2 hours
Reteplase	10 unit boluses 30 minutes apart

(0.9%).[46] Recent surgery is not an absolute contraindication and patients should have their individualised risks and the benefits weighed up; in shocked patients with massive PE the balance appears to be in favour of thrombolytic therapy for almost all patients.

If bleeding occurs, the thrombolytic therapy should be ceased, fresh frozen plasma should be given to replace coagulation factors and an antifibrinolytic drug (such as aprotinin) should be commenced.

SURGICAL EMBOLECTOMY

The merit of surgical pulmonary embolectomy, which has traditionally been seen as a life-saving option for moribund patients with massive PE, has been questioned since the advent of reliable thrombolytic therapy. Embolectomy surgery results vary widely and there has traditionally been an associated perioperative mortality of 25–50%. There is little reliable evidence comparing embolectomy and thrombolytic therapy. Mortality rates have been found to be lower when using a surgical approach combining rapid diagnosis, prompt surgical intervention and a high frequency of concurrent IVC filter placement.[47]

Surgical embolectomy should therefore be strongly considered in patients with PE and hypotension who have absolute contraindications to thrombolytic therapy, or if thrombolytic therapy has failed.[42] It may also be useful when patients have free-floating intracardiac thrombus.

PERCUTANEOUS EMBOLECTOMY

Percutaneous pulmonary embolectomy methods include either embolus extraction techniques (pure percutaneous embolectomy) or embolus disruption techniques (including catheter-directed thrombolytic therapy and percutaneous thrombus fragmentation techniques).[48] Success rates have been over 80% with reasonable complication rates, mostly from single-centre case series.[49] Randomised studies comparing percutaneous embolectomy with systemic thrombolytic therapy or systemic anticoagulation have not been done, so for now percutaneous embolectomy should be considered in patients with contraindications to systemic thrombolytic therapy who are in specialised centres.

CONCURRENT HAEMODYNAMIC SUPPORT

Shocked patients with PE (massive PE) need urgent haemodynamic support in addition to attempts at embolus destruction and prevention of further embolisation.

INTRAVENOUS FLUIDS

Volume loading can improve haemodynamic status in patients with massive PE, although if excessive then fluid therapy may worsen RV function, which can in turn affect LV function and become detrimental.[50] Cautious administration of small amounts of intravenous fluid should occur.

VASOPRESSORS

Ischaemia in the coronary circulation is an important factor in the haemodynamic instability of massive PE.[4] Embolus destruction (with thrombolytic therapy or embolectomy) should have the greatest effect on ischaemia reduction. However, elevation of the blood pressure and reduction in pulmonary and RV pressures may also be helpful, based on the rationale that the RV coronary perfusion pressure (RVCPP) can be severely impaired in massive PE.

RVCPP is estimated by the formula:

$$\mathrm{RVCPP} = \mathrm{MAP} - \mathrm{RVPm} \tag{34.1}$$

where MAP is the mean arterial pressure and RVPm is the mean RV pressure, all in mmHg.

RVPm can then be estimated by the formula:

$$\mathrm{RVPm} = \mathrm{CVP} + 1/3\,(\mathrm{PAPs} - \mathrm{CVP}) \tag{34.2}$$

where CVP is the central venous pressure and PAPs is the systolic pulmonary arterial pressure, all in mmHg.

When RVCPP falls as low as 30 mmHg (4 kPa) (normal being around 70–80 mmHg (9.31–10.64 kPa)), RV myocardial blood flow falls substantially and this contributes significantly to severe RV failure and shock. Efforts to elevate the MAP or reduce the PAPs should increase the RVCPP and therefore improve coronary blood flow to relieve ischaemia. Haemodynamic support for the shock state due to massive PE should therefore predominantly involve vasopressor drugs as these will predominantly increase MAP, and therefore RVCPP.

Norepinephrine (noradrenaline) is preferred to a pure alpha agonist such as phenylephrine, as cardiac output and RV myocardial blood flow effects are greater owing to the added beta-adrenoceptor agonist action. Dopamine, epinephrine (adrenaline) and vasopressin are reasonable alternatives to norepinephrine.

Although systemic vasodilators might improve the cardiac output in massive PE, they may be harmful overall as the MAP will either fall or remain constant at best and therefore the RVCPP will not increase. Isoprenaline, dobutamine, nitroglycerin, nitroprusside or milrinone should be considered only if the MAP is adequate and treatment is focused on cardiac output or pulmonary artery pressure.

Extracorporeal membrane oxygenation (ECMO) is an extreme but alternative form of mechanical assistance that may be available in more specialised institutions.[51] It should be considered for patients with PE who have had cardiopulmonary arrest or have very severe shock.

SELECTIVE PULMONARY VASODILATORS

Inhaled nitric oxide may be useful in patients with massive PE[51] by selectively decreasing pulmonary

arterial pressure with minimal effect on systemic haemodynamics. It may also assist in the severely hypoxaemic patient. Inhaled prostacyclin is an alternative.[52]

OTHER MANAGEMENT ISSUES

Oxygen should be supplemented to target adequate oxygen saturation. High flows may be required because of hyperventilation and the increased dead space. Intubation and mechanical ventilation are often necessary in patients with massive PE.

If chest pain is prominent, morphine should be administered. To guide resuscitation, it is useful to have at least a central venous catheter, particularly before thrombolytic therapy is given. Although there is increased risk of bleeding owing to the concurrent administration of thrombolytic therapy and/or anticoagulant therapy in these patients, this is probably outweighed by the importance of secure venous access and monitoring of the circulation in patients with haemodynamic compromise due to PE.

PREVENTION

Prophylaxis is probably the most important management aspect of VTE. All ICU patients should have an adequate assessment as to whether prophylaxis is warranted, although most should receive it using pharmacological thromboprophylaxis.[39] Careful attention to the intervention and dose is required, as omission of prophylaxis[53] and failure of prophylaxis[54] are common.

LMWHs have challenged traditional prophylaxis with fixed low-dose subcutaneous unfractionated heparin such that both are suggested alternatives for the prevention of VTE in critically ill patients.[39] Both therapies seem comparable for prophylaxis of DVT; however, rates of PE and HITTS were lower in a recent large study.[55]

Mechanical approaches (including graduated-compression stockings and intermittent pneumatic compression devices)[56] seem best utilised in patients who are bleeding or at major risk of bleeding. When bleeding risk decreases, pharmacological thromboprophylaxis should be commenced.
